The later studies have generally been semi-quantitative. When a rotating γ-camera has been used, the whole brain is scanned and the cerebellum has usually been chosen as the reference area, as it is relatively unaffected by the pathology of AD[12]. Also, patients with AD have a normal cerebellar metabolic rate of glucose, compared with elderly controls, on PET study[13]. A recent study validated the use of the cerebellum as a reference region for SPECT quantification in patients with AD[14]. Studies using dedicated head scanners, which acquire their data in the form of transverse tomographic slices, have not usually obtained cerebellar data, so they have used the occipital region as a reference area because the latter also appears relatively unaffected by AD[15]. These studies have consistently found that patients with AD have a bilateral decrease in rCBF in the posterior temporal and parietal regions, adjacent to the occipital lobe, and sometimes the frontal lobes are affected, although the basal ganglia are not (Table 67.1). Several studies have demonstrated correlations in AD between rCBF and neuropsychological function, and these have tended to be more apparent for language, praxis and global function than for memory[15,19]. Recent studies of AD have also evaluated the correlates of changes in CBF in relation to psychopathology and behaviour disturbance. Reduced frontal CBF in AD is associated with negative symptoms[20], with presence of delusions[24], disinhibited behaviour, apathy and blunted affect[22].

Pharmacological activation studies of the effect of central cholinergic stimulation upon rCBF in AD have recently been reported. These require paired SPECT studies, basal (after saline infusion) and activated (after infusion of a cholinergic agent, e.g. physostigmine). In patients with AD, the reduced rCBF in the posterior parietotemporal region in the basal scan was focally increased in the scan after the cholinergic agent, which did not occur in control subjects[19]. AD is associated with striking abnormalities in the central cholinergic system, of a functional cholinergic deficit that is at least partly reversible. Also a SPECT study of nootropic drugs showed regional improvement in CBF[23]. Donepezil treatment in AD was associated with a significant increase in CBF in the frontal lobes[24].

Studies have also addressed the diagnostic value of SPECT in differentiating AD from other types of dementia. Dementia with Lewy bodies (DLB) is associated with reduced frontal CBF than AD[25]. Importantly DLB is associated with severe degeneration of the dopamine system as shown by a recent SPECT study[26]. Primary progressive aphasia is associated with reduced CBF in fronto-temporal regions[27]. Fronto-temporal dementia FTD is characteristically associated with reduced CBF in fronto-temporal regions[28]. Alzheimer's disease and FTD could be differentiated by discriminant analysis applied to 99m Tc-HMPAO SPECT data with 100% correct classification of patients with FTD and 90% correct clarification of patients with AD[29].

Moreover fronto-temporal dementia is characterized by early non-cognitive behavioural changes with relatively spared cognitive function, frontal atrophy and SPECT deficits in CBF in frontal and temporal regions whilst AD is associated with early cognitive changes and medial temporal and parietal-temporal deficits in CBF[38].

Patients with Korsakoff's psychosis, in contrast to patients with AD, have normal rCBF in the posterior temporal region.

It is well established that Parkinson's disease (PD) is characterized by degeneration of dopaminergic neurons in the substantia nigra, which project to the corpus striatum. In an HMPAO SPECT study, 36 patients with PD were found, overall, to have normal rCBF in the caudate and putamen; however, those on no therapy had lower rCBF, and those on L-dopa-replacement therapy had higher rCBF, in the caudate and putamen, than controls. Bilateral reductions in rCBF in the parietal region, similar to those found in AD, were also found in patients with PD. No patients had focal lesions on CT scans. Interestingly, the parietal reductions in rCBF were more pronounced in those PD patients with cognitive impairment and those receiving chronic anticholinergic therapy. Dopamine deficiency is the main, but not the only, neurochemical deficit in PD, and these SPECT findings are consistent with the concept that AD and PD may overlap to some extent. Patients with Huntington's Disease (HD), characterized by chorea and progressive dementia, have reduced rCBF in the caudate nucleus, matched by caudate atrophy on MRI. However, the size of the rCBF deficit in the SPECT study exceeded that predicted by the MRI findings[39].

There has been a case report of a patient with pathologically proven Creutzfeldt–Jakob disease, who had strikingly reduced

rCBF throughout the cortex on HMPAO SPECT study, but a normal CT scan[40]. Patients with the AIDS dementia complex have been found, using SPECT, to have multiple or focal rCBF deficits, correlating with focal signs or symptoms, while CT scans showed diffuse cerebral atrophy[41].

DISCUSSION

Studies employing SPECT and PET can reveal cerebral abnormalities when CT and MRI do not, because the latter are measures of cerebral structure, while the former are measures of cerebral function. SPECT is, and is likely to remain, much more generally available than PET, but it is not currently capable of absolute quantification.

The characteristic SPECT findings in AD are bilaterally decreased rCBF in the parietal and temporal lobes adjacent to the occipital lobes, sometimes involving the frontal lobes, particularly in later cases. The primary motor, sensory and visual cortices and basal ganglia are relatively unaffected. This contrasts with typical CT findings of diffuse cerebral atrophy, although the CT scans have not generally been orientated along an axis that obtains optimum views of any focal atrophy in the hippocampus and temporal lobe[42]. However the Oxford Project to Investigate Memory and Aging (OPTIMA), which involved 200 patients with dementia and 119 normal controls evaluated annually till necropsy showed that medial temporal lobe atrophy (CT Scan), (80% diagnostic accuracy) and parietotemporal hypoperfusion by SPECT (83%) predicted the pathology of AD better than the established clinical criteria of NINCDS-ADRDA (66%) and DSM-IIIR (66%)[35]. On careful assessment, focal features can be seen on CT scans which correlate with individual symptoms, such as aggression or wandering[43], but the extent of the focal CT abnormalities is less than that seen on SPECT, and it appears that structural atrophy lags behind clinical deficit.

The diagnosis of dementia and its differentiation from other clinical syndromes, such as depression, is still primarily a clinical matter. If a structural lesion, such as a cerebral tumour, is suspected, then a structural scan, such as CT, is likely to be the best test for this. What, then, is the appropriate role of SPECT in current clinical practice in the assessment of dementia? The study by Upadhyaya *et al.*[34] suggests that it would be unwise to expect SPECT to assist in the differentiation of dementia from depression in the elderly because similar, albeit less marked, changes are seen in depression, as in AD. It would be interesting to know if those elderly individuals who present with the clinical syndrome of depression, and who have the characteristic AD abnormalities on SPECT, have a worse prognosis than those with normal SPECT scans. They might be individuals at risk of developing AD where depression has been one of the early clinical features, but much more information, including follow-up studies, is needed on this patient group to evaluate the utility of SPECT. More information is also needed on the frequency with which perfusion deficits (particularly those with a pattern similar to that in AD) are seen on visual inspection of SPECT studies in healthy, elderly controls. Patients with PD, particularly those who are cognitively impaired or receiving chronic anticholinergic treatment, also have similar SPECT abnormalities to patients with AD. Perhaps it is not surprising that there may be similarities on this measure of brain function, as there can be a degree of overlap of the clinical syndromes.

If the clinical diagnosis of dementia is made in an individual patient and it appears to be a primary degenerative dementia, the SPECT study can add weight to the clinical impression that the underlying diagnosis is that of AD, frontal lobe dementia (FLD) or progressive supranuclear palsy (PSP). AD is most characteristically associated with posterior rCBF deficits, while FLD and PSP are strongly associated with anterior rCBF deficits and themselves have distinctive patterns when CT scans are not particularly helpful in this situation. Similarly, Korsakoff's psychosis appears to be more characteristically associated with frontal rCBF deficits than posterior temporal deficits[17]. SPECT can also assist the clinical assessment in the differentiation of AD from MID: bilateral parietotemporal deficits are strongly suggestive (but not diagnostic) of AD, although it must be remembered that AD and MID coexist in a substantial minority of cases. There is no particular single pattern of rCBF deficits seen in MID. SPECT findings vary from normal to asymmetrical deficits and theoretically MID could mimic any other pattern. However, if an asymmetrical pattern is found affecting areas other than the parietotemporal region, it is suggestive of MID. This impression is strengthened if the rCBF deficits coincide with cerebral infarcts seen on structural imaging with CT or MRI. If a patient with relatively advanced dementia has a normal SPECT, it is unlikely to be AD and may be consistent with MID.

All these conclusions, however, must be tempered by the knowledge that our present association of SPECT and PET patterns with specific conditions is based on studies where clinical diagnoses of patients are made initially and are then correlated with the SPECT findings. We need follow-up studies and pathological findings at post mortem to make more definitive assessments of the significance of specific SPECT patterns. Indeed a recent study evaluated early AD (mild cognitive impairment) using brain perfusion SPECT who were diagnosed to have AD 2 years later with a follow-up SPECT[44]. Selective reduction in CBF was observed in the left hippocampus and parahippocampal gyrus in the follow-up SPECT. We could also learn whether SPECT studies can help predict clinical outcome in individual cases. There is evidence from PET studies of patients with early AD that focal cortical reductions in glucose metabolism precede the appearance of focal neuropsychological deficits.

However, if the early whole-brain studies are correct and the metabolic rate of glucose is uncoupled from CBF in early AD, such that it is decreased relative to CBF and the rCBF is reduced later in the course of the disease, SPECT might have different predictive power in comparison with PET in early AD. It is possible that patients at risk for HD may be diagnosed in the presymptomatic phase by the SPECT finding of reduced rCBF in the caudate nucleus.

It is clear that SPECT will be used substantially in further research in AD. More significant advances in our knowledge of AD are likely to come from follow-up and activation studies. The latter would involve paired SPECT studies, basal and activated, and the activation could be cognitive or pharmacological. For paired studies, the important measure is the difference in rCBF between the two SPECT studies, which indicates the effect of activation. This avoids the problem of variation in basal values between individuals and the problem of the effect of an uncertain degree of cerebral atrophy upon rCBF. The semiquantitative measures of SPECT are adequate, and may be preferable, for this analysis. Cognitive activation studies in controls and in patients with AD would provide a better understanding of the cerebral processes involved in cognitive function in normal individuals, and knowledge about the form of disruption of these processes in disease. Pharmacological activation studies would enable direct measures of specific neurotransmitter function to be made and hence the pharmacological characterization of disease in an individual, with implications for treatment and prognosis[19].

Another promising direction for SPECT is the study of neurotransmitter receptors. The radioligand ^{123}I-QNB has been developed for the measurement of muscarinic cholinergic receptors and it has been used in the study of AD[3]. Currently it requires a radiochemist on site to produce ^{123}I-QNB, and so it is not commercially available, but the development of radioligands for

general use in receptor studies is likely to continue and may further extend the role of SPECT.

Nosology and Classification of Mood Disorders

Dan G. Blazer
Duke University Medical Center, Durham, NC, USA

The mood or affective disorders are a group of disorders characterized by disturbance of mood and accompanied by a partial or complete change in mood or affect that is either manic (or hypomanic) or depressed (or mildly dysphoric). These disorders are classified in both the DSM diagnostic system and the ICD diagnostic system in the three-digit rubic of 296[1,2]. There have been recommendations for changes in the ICD system from ICD-9 to ICD-10 that would reclassify some disorders previously classified elsewhere (such as neurotic depression, 300.4) to the mood or affective disorders. Another minor change in the new ICD diagnostic system (already represented in DSM-IV) is replacing the title "affective disorder" (affective psychosis) with "mood disorder". With some exceptions noted below, the nosology of mood disorders in ICD-10 and DSM-IV is appropriate for the classification of mood disturbances in older adults. The classification of the disorders will therefore be described below, with specific comments related to older adults.

MANIC EPISODE

A manic episode is characterized by an elevated mood that is unrelated to the patient's circumstances. This elevated mood usually varies from an expansive or irritable syndrome to an almost uncontrollable excitement and psychotic agitation. Changes in mood are accompanied by increased energy, a decreased need for sleep, a decline in normal social inhibitions, as well as inflated and grandiose ideas, which frequently become delusional. Older persons can experience a typical episode of mania as well as hypomania (a less severe elevation of mood) but are more likely to suffer a so-called "irritable" or "angry" manic episode. Joviality and elation are replaced by irritability and agitation (as described elsewhere in this text). Nevertheless, older persons who suffer manic episodes usually meet both ICD-I0 and DSM-IV criteria, even when the predominant symptoms are irritability and anger, as other diagnostic criteria are met.

DEPRESSIVE (OR MAJOR DEPRESSIVE) EPISODE

A major depressive episode is characterized by a depressed, disinterested or irritable mood, associated with the loss of interest or pleasure in all or almost all activities, accompanied by a number of other symptoms. These additional symptoms include a reduced capacity for enjoyment, reduced interest in surroundings, difficulty concentrating, lethargy, sleep disturbances, appetite disturbances, decreased self-esteem and self-confidence, and frequent ideas of guilt or worthlessness. Although older persons are somewhat less likely to report a specific decrease in their mood, they almost always describe a loss of interest in usual activities (anhedonia) in the midst of a major depressive episode. The categories of severe depressive episode in ICD-10 and major depressive episode in DSM-IV are very similar. DSM-IV criteria permit the diagnosis of a minor depressive episode, that is, a depressive episode which fulfills some of the symptom criteria for a major depressive episode and/or dysthymia and which lasts 2 weeks or longer. The more severe consequences of a depressive episode, such as a successful suicide or a retardation that progresses to stupor, would be characteristic of a severe but not a mild depressive episode in ICD-10.

Older persons who suffer a complicated, severe depression are easily diagnosed according to both ICD-10 and DSM-IV criteria. Problems do arise, however, when the episode experienced by older persons is accompanied by a severe medical illness or significant cognitive impairment. The frequency of psychobiologic symptoms in more severe depressions renders the distinction between symptoms of depression and symptoms of physical illness/functional impairment difficult in the midst of a depressed mood associated with medical illness. The current nosology is not helpful in disaggregating mood disorders from either the symptoms of physical illness or normal psychologic reactions to physical illness. Some have suggested that a unique rating for older persons for depression should include a measure of cognitive functioning (but this is yet to be included in any extant diagnostic system). The co-morbidity of depressive symptoms in organic mental disorders such as dementia, Parkinson's disease and stroke renders such an approach potentially useful in improving the current nosology. Major (or severe) depression can be specified as severe, with or without psychotic features in DSM-IV. Psychotic depression is relatively more frequent in the elderly and the recognition of psychotic features may direct the specific therapeutic intervention considered by the clinician.

BIPOLAR AND UNIPOLAR DISORDER

In both ICD-10 and DSM-IV, individuals who present with a history of recurrent mood disorder (at least two), in which mood and activity were profoundly disturbed and at least one of the episodes is manic, are classified as suffering from bipolar mood disorder. Bipolar disorder usually has an early age of onset, although it can have its onset later in life, and the categorization is useful in older as well as younger persons. Bipolar disorders are

classified as manic (the individual is currently in a manic episode), depressed (the individual is currently in a depressed episode and has at least one well-authenticated manic episode in the past), or mixed (the individual's current episode involves a full symptomatic picture of both manic and depressed episode, except for the duration requirement of 2 weeks of depressed episodes). Symptoms are often intermixed or rapidly alternating within hours or days in the latter category.

Bipolar II disorder is characterized by at least one hypomanic episode and at least one episode of major depression. These disorders are probably more common among older persons than the more classic bipolar disorder described above. Older persons frequently experience depression and occasionally mania secondary to medical illness or medications, categories which are specified in DSM-IV as mood disorder due to a general medical disorder and substance-induced mood disorder. Common examples of causes of these secondary mood disorders in the elderly include hypothyroidism. Parkinson's disease, chronic obstructive pulmonary disease, various forms of cancer, alcohol, β-adrenergic blockers and L-dopa. Mood disorders with a seasonal pattern are less frequent in the elderly.

Individuals who never experience an episode of mania or hypomania but nevertheless suffer episodes of major depression are generally classified as "single-episode" or "recurrent". Most depressive disorders are recurrent, that is, if an individual (regardless of age) suffers an episode of major depression, the chances are high that he/she will suffer an additional episode at some time in his/her life. Recurrent or persistent depressive episodes are not always easily classified, that is, distinct episodes of major depression followed by distinct episodes of normal functioning may be the exception rather than the rule. For this reason, additional diagnostic categories have been instituted in the nosology to disaggregate the classification of the natural history of depressive episodes. In ICD-10, a category of "recurrent severe depressive disorder" is analogous to the DSM-IV category of "major depression, recurrent". Recurrent mild depressive disorder is categorized in ICD-10 by repeated episodes of depression, the majority of which fulfill the description given for mild depressive episode above. These recurrent mild episodes may or may not be associated with environmental stress and may be either acute or insidious in onset. Recovery is usual, although not always complete.

Cyclothymia is included in both DSM-IV and ICD-10. According to ICD-10, cyclothymia is a persistent instability of mood involving numerous periods of mild depression and mild elation. The instability usually develops early in adult life and pursues a chronic course, although at times mood may be normal and stable for months. Cyclothymia is difficult to establish without a prolonged period of observation or an unusually good account of the subject's past behavior. In DSM-IV, cyclothymia must persist for at least 2 years to be diagnosed and involve numerous hypomanic episodes.

Yet another phenomenon has emerged in the study of the natural history of depression—rapid cycling. Rapid cycling is the occurrence of four or more episodes of depression or mania per year, with either 2 weeks of normal mood between episodes, or a shift directly from mania to depression, or vice versa. Others have classified rapid cycling as involving either mixed mood states, or frequent mood fluctuation without discrete intermorbid periods, or involving 24 or 48-h cycles of mood disturbance. Rapid cycling occurs in persons regardless of age, although there may be some tendency for individuals to decrease their propensity to rapid cycling with increased age. Rapid cycling appears to be more common in individuals with bipolar disorder than unipolar disorder, but it is not limited to individuals with bipolar disorder. Rapid cycling is a specifier of bipolar mood disorder in DSM-IV.

DYSTHYMIA

Dysthymia is a category included in both ICD-10 and DSM-IV. Dysthymia is a chronic depression of mood which does not fulfill the description and guidelines of mild recurrent depressive disorders (in ICD-10) and is characterized by periods of days or weeks at a time when patients feel tired and depressed, where everything is an effort and where nothing is enjoyed. They "brood and complain", sleep badly and feel inadequate, but are usually able to cope with the basic demands of everyday life. This description is similar to the description of dysthymia in DSM-IV, where the essential feature is a chronic disturbance of mood, involving a depressed mood for most of the day and more days than not for at least 2 years (the 2 year minimum duration is not a criterion in ICD-10). In addition, individuals suffering dysthymia suffer many of the symptoms of the more severe depressions, but with less severity, such as poor appetite, insomnia, low energy and low self-esteem. Older persons often meet criteria for a dysthymic disorder when diagnosed with major depression. It is often difficult to determine, however, whether the dysthymic disorder is a separate entity or whether it is part of the same syndrome which "waxes and wanes" in severity. Recent studies have suggested that dysthymic disorder may exist most often in the elderly as an entity not associated with major depression. Dysthymic disorder has usually been equated with depressive neuroses, as described in earlier versions of both the ICD and DSM diagnostic systems, which assumes that the depressed mood results from psychoneurotic and stress-related difficulties.

Yet another category which has been suggested is minor or mild depression. Criteria for minor depression can be found in the appendix of DSM-IV and variants can be found in the Research Diagnostic Criteria and in ICD-10. There is virtually no data to substantiate a specific entity for minor depressions, except that persons who experience minor depression (that is, symptoms less severe than major depression for at least 2 weeks, according to DSM-IV) exhibit a similar risk factor profile and are at much greater risk for developing major depression over time. There have been a number of studies of minor depression (see Chapter 71) among the elderly. The renewed interest in minor depression once again brings the categorical vs. continuum controversy to the forefront in the phenomenology of depression.

ADJUSTMENT DISORDER WITH DEPRESSED MOOD

In the DSM-IV system of classification, an adjustment disorder is a reaction to an identifiable psychosocial stressor that leads to maladaptive reactions, including impairment in occupational functioning and symptoms that are in excess of normal and expected reaction to this stressor. The maladaptive reaction may take many forms and an exaggerated depressed mood is one of the forms.

Symptoms of adjustment disorder with depressed mood include tearfulness and feelings of hopelessness. By definition, the maladaptive reaction can persist no longer than 6 months, does not meet criteria for other disorders and does not represent uncomplicated bereavement. ICD-10 includes the category of adjustment disorder and the clinical form may take the characteristic of a "prolonged depressive reaction", that is, a mild depressive state occurring in response to prolonged exposure to a stressful situation but of a duration not lasting 6 months. The categories of adjustment disorder are therefore very similar for both diagnostic systems. In theory, the stressor may include physical illness and therefore this category is most relevant to depressive episodes in later life. A lack of acceptable longitudinal data on the association of depressive symptoms with physical

illness renders it difficult to determine whether older persons do recover from the depressive episode, which often accompanies a physical illness within the 6 months required by the diagnostic category of adjustment disorder.

DEPRESSED MOOD ASSOCIATED WITH DEMENTIA OF THE ALZHEIMER'S TYPE AND VASCULAR DEMENTIA

DSM-IV provides for the classification of dementia of the Alzheimer's type (both early and late onset) as ''with depressed mood as well as vascular dementias''. The frequency of co-morbid depression and cognitive impairment renders this classification a common one among dementia patients. As the actual pathophysiological and psychopathological relations between depression and cognitive impairment are unclear, the simple recognition of the co-morbidity is sufficient. For example, the depression may be a reaction to cognitive decline or an actual symptom of the underlying disease process, which also causes the cognitive problems. Some recent studies have suggested that a separate category of vascular depression be introduced. This condition is present when individuals meet the criteria for major depression and have MRI-confirmed vascular brain changes. Persons with vascular depression appear to have more symptoms of apathy (perhaps due to disruption of prefrontal systems or their modulating pathways) and may be at increased risk of non-recovery.

CONCLUSION

In general, the current classificatory system of both DSM-IV and ICD-10 work relatively well for classifying older persons suffering from mood disorders. A number of distinct exceptions must be recognized, however. Categories such as dysthymic disorder, adjustment disorder and minor depression in DSM-IV do not appear to be adequate, and therefore more exploration of the ICD-10 construct of mild depression (but possibly not utilizing the specific diagnostic criteria of ICD-10) would appear in order. A major problem with the current classification systems is the inability to take into account co-morbidity, especially co-morbid depression and physical illness. Co-morbid depression and physical illness is a grossly unstudied area, compared to the clinical relevance of the condition. To what extent do our current classification systems accommodate individuals suffering mild or even severe depressive symptoms in the midst of physical illness? In addition, depression is often co-morbid with other psychiatric symptoms, especially anxiety disorders and somatic complaints. Neither ICD-10 nor DSM-IV adequately accommodates the co-morbid psychiatric syndromes that are frequently seen in older adults.

Finally, when classifying mood disorders, many individuals suffer a depressed mood in late life that is not disordered. Uncomplicated bereavement is an expected accompaniment of older persons who experience a significant loss in old age. In addition, other older persons may become demoralized, given the current circumstances in their lives. Such persons should not be classified in a disease-orientated classification system. Nevertheless, these human experiences are not to be ignored by the clinician working with the older adult suffering a mood disorder.

Genetics of Affective Disorders

John L. Beyer and David C. Steffens

Duke University Medical Center, Durham, NC, USA

The observation that affective disorders aggregated in families has been present from the time of Socrates, through the analysis of Sigmund Freud, the behavioral work of B. F. Skinner and in the genetic studies of the past 40 years. In each of these views, the family unit recurs as a major focal point in mood disorders. But how is one to understand this relationship? Affective disorders may be aggregated in families for a variety of reasons, such as shared genes, shared culture, shared adversity, or multiple other reasons.

In the past, research in families followed two non-overlapping tracks: genes and environment. This was known popularly as "nature vs. nurture." In recent years, researchers have become more aware that attempts to dichotimize the cause of affective disorders into "genes" and "environment" has hindered understanding of mood disorders. The emerging science of genetic epidemiology focuses on causes, distribution and control of disease in groups of relatives, and with inherited causes of disease in populations[1]. Thus, the goal of genetic research is to identify both genetic and environmental causes of illness. In fact, certain types of genetic studies (e.g. twin studies) have provided some of the strongest evidence that environment plays a significant etiologic role in the expression of mental illness.

Research findings clearly show that the etiology of mood disorders in early and middle adulthood is multifactorial. Both environmental factors (e.g. parental loss, stroke) and genetic factors are strongly implicated, although what occurs and how this happens remain as areas of intense research. In recent years, investigations in late-life affective disorders have asked the same questions regarding cause, but the answers suggest that there are etiologic differences among affective disorders at different ages. This observation only leads to new questions. Is the development of late-life affective disorders related to the genetic make-up of the individual? Are late-life affective disorders a continuation of mood disorders which developed earlier in life or do they represent unique reactions to specific challenges presented by the process of aging? If so, what are these challenges and how are they related to an individual's genetic make-up? How do genetic and environment factors contribute to the understanding of diagnostic subsets of affective disorders?

In this chapter, we will review the current state of genetic research of affective disorders, primarily studied in early and middle life. Then we will contrast that with what is known about affective disorders that have their first onset in late life. Finally, we will discuss the implications of these findings and suggest a theoretic framework to understand genetic and environmental contributions to geriatric affective disorders.

GENETIC INFLUENCES IN AFFECTIVE ILLNESS

There are four types of studies that demonstrate the influence of genetic factors on the development of disease: (a) studies of familial aggregation; (b) twin studies; (c) adoption studies; and (d) association and linkage studies of an illness with a genetic marker.

Family Studies

Family studies are the most basic research form in evaluating genetic risk. They attempt to answer the question, "Does this disorder run in families?" Logically, if genes cause a disorder, then relatives of an individual affected by that disorder (the proband) should be more likely to have that particular disorder than others in the general population, since they share common genes. However, common environmental factors may also contribute to the clustering in families. Therefore, the major goal of family studies is to understand the magnitude and patterns of a disease's aggregation, rather than identify specific genetic causes.

In affective disorders, six landmark studies[2–7] have supported the observation of familial aggregation. First-degree relatives (parents, siblings, offspring) of depressed patients are twice as likely to develop depression than those in the general population. First-degree relatives of bipolar patients are at even greater risk for developing bipolar disorder (incidence of 3.7–17.5%, depending on the study). The risk of bipolar disorder is less in second-degree relatives (grandparents, grandchildren, aunts, uncles) of bipolar patients, although still elevated over the general population.

Twin Studies

Twin and adoption studies are especially helpful in answering the next question, "What are the relative contributions of genes and environment to the development of a mental disorder?" Twins provide a natural experiment in genetics. Monozygotic (MZ) twins, known as identical twins, share 100% of their genes. Dizygotic (DZ) twins, known as fraternal twins, share approximately 50% of their genes, the same proportion as with other siblings. In the "twin experiment", it is assumed that both dizygotic and monozygotic twins share the same environment, but only monozygotic twins share the same genes. Thus, if genes are a putative cause for a disorder, then the MZ co-twin of a proband should be at higher risk to develop a disorder than the DZ co-twin of a proband. This is expressed as the concordance rate.

In affective disorders, the average concordance rate for bipolar disorders in monozygotic twins was 60%, while the concordance rate in dizygotic twins was 12%[8]. The five-fold greater rate of concordance strongly indicates the importance of genetic factors in the familial aggregation. For major depressive disorders, the role of genes is much weaker. Two recent twin studies[9,10] found that the relative risk for monozygotic twins was 1.9, while the risk for dizygotic twins was 1.2. Both findings of heritability were statistically significant.

Adoption Studies

Adoption studies provide a powerful method of evaluating genetic and environmental contributions to the familial aggregation of disease. In these cases, adopted children have a genetic relationship with their biological family, but share the primary environmental relationship with their adopted family. Thus, if genes are responsible for the familial transmission of a disorder, then the risk for the adopted child should more closely match the risk of the biological family. However, if environmental factors are more responsible, the relative risk of the adopted child would match the risk of the adoptive family.

In affective disorders, five studies have reviewed adoption and incidence of affective illnesses[11]. Two of these studies have demonstrated strong genetic influences, while the others show a more variable response. One adoption study[12] suggested certain environmental influences, especially parental loss and parental alcoholism, as predictors of depression.

Genetic Markers and Linkage Studies

The most specific studies for genetic involvement are genetic marker and linkage studies. Genetic markers are specific areas on the chromosome where laboratory procedures may differentiate individuals on the composition of DNA at that location. They are used to identify where a specific gene may be on a chromosome. Linkage refers to the nearness of two or more genes or markers on a chromosome. Linkage studies are based on the principle that as the genetic distance decreases, the probability that they will be inherited increases.

A number of gene loci for affective illness have been proposed through linkage work, but the results have been disappointingly inconsistent, and a number of the most striking findings have proven controversial[13]. One possible exception is a small subset of bipolar disorders that may be X-linked[11,14]. Recent investigations in an ethnically homogeneous American Amish population initially suggested linkage to a marker on chromosome 11[15]. Unfortunately, more recent work has cast doubt on this conclusion[16] and has prompted greater caution generally in the interpretation of the linkage results in psychiatry.

LATE-LIFE AFFECTIVE DISORDERS

Just as affective disorders in early and middle life are quite heterogeneous, late-life mood disorders are also a heterogeneous entity. However, it is unclear whether late-life affective disorders comprise the same notions of heterogeneity as those in early and middle life. In late-life mood disorders, two groups of patients are usually differentiated: those who had an early-onset of illness and continue to have symptoms or episodes in their later life, and those who had a late-onset of illness (usually defined as a first onset after the age of 60 years).

Mendlewicz[17] and other researchers have suggested that the age of onset is an important clinical variable in the genetic study of affective illness. When differentiated by age of onset, late-onset depressive disorders have qualities that suggest they may be genetically different from early-onset forms. These characteristics include the non-conformity of affective disorders to expected genetic models and clinical differences observed between late- and early-onset depression.

Most genetic models propose that strong genetic influences are most often found in the most severe forms of an illness and in the early expressions of the illness. However, late-onset affective illness syndromes are typically among the severest and most refractory to treatment[18,19]. Older patients with affective disorders who require hospitalization tend to have a slower resolution of symptoms and a longer duration of hospitalization than younger adult patients[20]. Further, patients with late-onset depression and bipolar disorders have less familial aggregation of mood disorders than those with the early-onset affective disorders. This finding has been extensively validated in many studies[21–26]. Late-onset mood disorders are also less likely to display the gender disparity[21] present in early-onset mood disorders.

Clinically, patients with late-onset mood disorders tend to have increased impairment on neuropsychological testing and higher rates of incident dementia noted at follow-up[27]. While inadequate support appears particularly difficult among middle-aged patients, stressful life events appear to pose the greater risk of poor outcomes among geriatric patients[28].

Gatz *et al.*[29] studied the characteristics of depression in a sample of elderly reared-apart and reared-together Swedish twins. They found evidence of only limited heritability (16%). In contrast a study[30] of a sample of Danish twins 75 years of age and older found that depression symptomatology is moderately heritable in late life (approximately 35%). However, both studies consistently implicated environmental factors as the major source of variance in depression symptoms among the elderly.

GENETICS OF LATE-LIFE AFFECTIVE DISORDERS

How can one understand the differences noted above, and how are they important for the genetic study of late-life mood disorders? Two explanations have been proposed for the age-related variation in genetic influence for affective illnesses: multifactorial inheritance and increased phenocopy expression with age. Multifactorial inheritance (also called polygenic inheritance) suggests that inheritance patterns are a result of a combination between multiple interacting genes and environmental factors. Examples of traits that have multifactorial inheritance include stature, intelligence and blood pressure[17].

According to the multifactorial theory, the onset of an affective disorder results from the additive effects of several genetic and environment factors. This concept is graphically illustrated in Figure 69.1. The horizontal axis represents the level of genetic predisposition, while the vertical axis represents the level of environmental risk. Thus, the more factors present (the number of implicated genes or environmental events that contribute to an affective illness), the more likely an individual would develop an affective illness and the more severe that illness would be. One could also assume that early-onset illnesses probably result from greater genetic loading, while late-onset illnesses may have less genetic loading but increased occurrence of environmental events with age.

The second explanation, increased phenocopies, illustrates the limited specificity of the affective disorders diagnosis. Both bipolar disorder and major depressive disorder are syndrome diagnoses, that is, the diagnosis is based on the presence of a collection of observed symptoms (phenotype) rather than an etiological cause. In this theory, late-onset affective illness is a collection of phenocopies. Phenocopies are illnesses with a

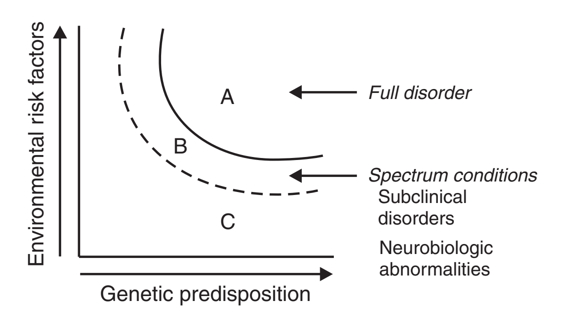

Figure 69.1 How genes and environment lead to illness. Adapted from Faraone *et al.*[31]

characteristic phenotype but different underlying causes. Hypothyroidism is an example of a phenocopy. Individuals with hypothyroidism may meet major depression criteria, but they require quite different treatment.

It should be noted that the two explanations postulated for the observed differences in age-related affective disorders are not mutually exclusive. We have already noted that affective disorders are heterogeneous. Figure 69.2 demonstrates two dimensions of heterogeneity—clinical and causal. Clinical heterogeneity occurs when more than one clinical condition can occur by the same cause. Causal heterogeneity occurs when two or more causes can independently produce the same clinical syndrome[31]. In Figure 69.2 the small circle at the top represents all patients who have the full disorder (in this case, bipolar disorder or major depressive disorder). The larger circle demonstrates three outcomes attributed to disease genes: "full disorder", "spectrum conditions" and "symptom-free". Some individuals with the disease genes will develop the full disorder. Others will not meet criteria for the full disorder, but will show abnormalities and trends toward the disorder. These are called "spectrum conditions". Finally, some individuals will remain symptom-free despite carrying the same disease genes.

The small circle at the top of Figure 69.2 also shows that not all patients who have the full disorder have the disease genes. This subgroup represents those patients with phenocopies of the full disorder. They have an illness that looks like a genetic disorder but it is not caused by genes, at least not the same disease genes.

It has long been known that depressive syndromes are very common in neurological disorders such as Parkinson's disease, Alzheimer's disease and stroke. More recently, researchers[32,33] have proposed a subtype of depression called "vascular depression", based on the presence of white and gray matter changes observed on magnetic resonance imaging (MRI) scans. These changes are frequently seen as patients age, and both the pattern and intensity of lesions appear to have a direct relationship to major depressive episodes (and possibly bipolar disorder). This subtype is differentiated from other depressive types by demonstrating a constellation of depressive symptoms, increased incidence of apathy, psychomotor retardation, cognitive impairment, functional disability and a decreased incidence of familial affective disorders. If this is shown to be true, then the age-related variation in late-life affective disorders may be explained by increasing phenocopies in older adults who have late-onset affective disorders. Patients with early-onset affective disorders (which would include elderly patients with previous diagnosis of affective disorders) may be more likely to have a genetic cause.

As research like this sharpens our understanding of disease, the "heterogenous" group of affective disorders will be differentiated into various subtypes, each with a more specifically defined course, prognosis and treatment. Each new subtype will also suggest new ways that genes and the environment may contribute to the expression of the illness. For example, current research is examining how other "disease genes" may cause various phenocopies. One of the major complications of Alzheimer's disease is the development of a major depressive disorder. Research has suggested that the presence of one of the ApoE alleles, which has been implicated in Alzheimer's disease and is genetically determined, may predispose patients to the development of major depression[34,35]. Other researchers have not found this finding to be consistent[36–38]. However, the implication is clear. Environmental and genetic patterns in late-onset affective disorders are emerging that are different from patterns seen in early-onset disease.

Environmental Factors, Life Events and Coping Abilities

Toni C. Antonucci and James S. Jackson
University of Michigan, Ann Arbor, MI, USA

Understanding environmental factors, life events and coping abilities in the lives of older people is best accomplished by applying a life-span developmental perspective. Baltes *et al.*[1] emphasize that people evolve throughout their lifetime and become more heterogeneous with age. As people grow older, the experiences of a lifetime combine uniquely to shape them. This is especially important to the question of how individuals cope with the challenges of old age. The lifespan framework allows us to incorporate information about an individual's experiences, the successes or failures an individual has had in coping with these experiences, and the people who have or have not been helpful in aiding the individual to achieve those successes. Social support is not always or solely considered a coping ability or strategy. However, it has been argued that successful coping is the ability to activate the kinds of support needed to meet the needs of specific situations and to help the individual achieve a positive affective disposition.

The Convoy Model of Social Relations[2,3] suggests that individual and situational characteristics combine to explain and predict the amount, type and adequacy of support an individual is capable of garnering to cope with life events and circumstances, thus enabling the individual to adapt successfully to life's challenges. The individual moves through time and circumstance surrounded by a "convoy" of people, who either help or inhibit the individual's ability to successfully cope with the problems he/she faces, consequently affecting both his/her health and well-being. The Convoy Model incorporates both personal and situational factors to predict coping skills and success. Available evidence indicates that most convoys consist of both family and friendship relationships within a multigenerational context.

These contexts are characterized by exchanges that are perceived as either reciprocal or non-reciprocal. Since reciprocity is the norm of social relationships[4], it is useful to consider how people assess the reciprocity of their relationships. As one gets older, it is often the case that one requires more support, both emotionally and instrumentally, to cope with the challenges of life. There is some danger that older people will come to perceive their relationships as non-reciprocal, and feel that they are over-benefited, i.e. receive more support than they provide, by these exchanges. There would then be the danger that this will lead to a sense of indebtedness. However, many people are quite resourceful about maintaining relationship equity by using what has been termed a "support bank"[3] accounting system. Older people have been known to consider support provided by them to others earlier in life as contributions to a "support bank" from which they can make withdrawals, as needed, later in life. This interpretation of support exchanges can be especially useful for understanding how some older people cope with crises by accepting considerable support from others but without the disadvantage of feeling overly indebted by the receipt of more aid than they are currently able to reciprocate. Also interesting is the phenomenon whereby the older person recalibrates support received of one type to equal support provided of another type. Thus, a drive to the doctor's office can be completely reciprocated by a freshly baked loaf of bread. Some might argue that the ability to cognitively construct an equitable exchange is not necessarily a reality assessment, but rather an exercise in adaptive illusions[5].

Several recent theoretical developments should be noted. Baltes and Baltes[6] have proposed the Selective Optimization with Compensation Theory. This theory suggests that an important strategy of successful aging is to carefully select those behaviors, goals or activities that are personally most important, and to develop multiple strategies to compensate for the limitations increasingly evident with age. This theory suggests that some goals will be ignored, dropped or otherwise disregarded, while others will be achieved but only through compromise and compensation. A related theory has been proposed, the Socio-emotional Selectivity Theory[7]. This theory focuses specifically on social relations and suggests that, with age, people reduce the number of social relationships in which they invest time, energy and emotional commitment, to only those which are truly close and important to them. The argument suggested is that with fewer years left to live, older people are less interested in relationships that are troublesome or otherwise unsatisfying to them and more interested in maximizing their time and commitment to those relationships that are truly important to them. It could also be that individuals are selected who allow the elder to maintain reciprocity or those with whom the elders have had a particularly satisfying exchange relationship in the past. Empirical data are available to support both perspectives. Especially interesting, in light of the Socio-emotional Selectivity Theory, is the finding that older people report significantly fewer negative social relations and are more satisfied than younger people with the relationships they do have.

We know that people vary in their ability to cope with the problems they face and in their ability to develop supportive relationships. We can best understand these differences as indications of how older people differentially experience their environments and life events and how they cope with these experiences. Although it is clearly true that some people experience more crises than others, it is not always the case that those who experience a great many crises are the ones

overwhelmed by them. The same environmental conditions or life events that might devastate one person may have less of a negative impact on another.

The Support/Efficacy Model[8] proposes a lifespan framework to explain these differences. This model suggests that supportive interactions over time are essential to developing in the individual a sense of efficacy that instills in that person the belief that he/she can successfully meet the challenges of life. With time, exchanges and interactions accumulate which either lead the individual to feel competent and capable of coping with the problems he/she confronts (i.e. efficacious) or, under less optimal circumstances, leaves the individual feeling overwhelmed by, and personally incapable of, coping with the problems and circumstances of life.

It is also important to consider the influence of non-psychiatric factors on the experience of events in old age and how one copes with stress. Jackson *et al.*[9] have noted that racial, cultural and other sociodemographic factors fundamentally affect how a situation is experienced. If an individual is one of many suffering the same negative experience(s), the etiology of that experience may not be devastatingly personalized. On the other hand, if everyone else in one's reference group is significantly more successful, the relative comparison can be devastating, even if "objectively" the situation is quite positive. Similarly, there now exists empirical evidence indicating that different national groups appear to vary considerably in the degree to which they respond negatively to environmental factors and life events. Fuhrer *et al.*[10] have shown that normal French elderly score markedly higher on measures of depressive symptomatology than their American counterparts, despite the fact that their general environmental circumstances and their experienced life events are actually quite similar. Antonucci *et al.*[11], comparing Black and White Americans with French elderly on a variety of factors, have shown that the general mental health of American and French elderly are similar in some respects and different in others. All three groups are negatively affected by functional limitations. On the other hand, Black American and French elderly men are less satisfied with life than women in these groups, although there is no sex difference among White Americans. A recent study of the elderly in the Netherlands and Italy[12] is also of interest. It suggests that objective characteristics, such as living arrangements, which some might consider indicators of coping, need to be understood in terms of the individual's psychological state. Dutch elders tend to live alone, while Italians tend to live with their families. However, Italian elders reported less social integration and more loneliness than Dutch elders. Despite the appearance of family integration, these data suggest that an individual's ability to cope with environmental factors is not always directly predictable from the objective characteristics of the situation. As with the French and Americans reporting of depressive symptomology, this could simply, but importantly, be a difference in expressive style.

It has been suggested that an individual's ability to cope with specific environmental conditions and life events is best understood through a consideration of the resources and experiences available to that person. One simplistic way to consider this is that successfully coping with stresses and strains in early life is the best predictor of the individual's ability to cope with stressful situations in later life. This is likely to be true, even if the exact nature of the stressful event varies. There is also reason to believe that some individuals develop coping styles over their lifetime that can be seen to be generally successful and adaptive, while others develop coping styles that are generally unsuccessful or maladaptive. At best, these coping strategies match the environmental conditions and life events that the individual experiences. For example, Jackson[13] and Jackson *et al.*[14] have argued that the harsh environmental conditions faced by many racial and ethnic minorities lead to the development of novel and effective coping strategies. Over the lifecourse, however, many of these strategies actually may be deleterious to health status, e.g. alcohol use. Although the specific nature of these experiences will change with age, an individual's ability to cope with these environmental events is likely to show fairly stable lifespan continuity. At the same time, as research clearly demonstrates, individual coping and adaptation competencies can be improved through informal and professional intervention at all points in the individual lifecourse.

The Aetiology of Late-life Depression

Martin Prince and Aartjan Beekman

Institute of Psychiatry, London, UK

It is vain to speak of cures or think of remedies, until such time as we have considered of the causes (Galen)

Empirics may ease, and sometimes help, but not thoroughly root out . . . as the saying is, if the cause be removed, the effect is likewise vanquished (Burton, *The Anatomy of Melancholy*)

Late-life depression, when defined according to the broad criterion of clinical significance, is a common disorder affecting 10–15% of the 65+ population[1,2]. Prevalence rates for major depression are substantially lower, but this category excludes common forms of late-life depression, particularly those associated with bereavement and physical co-morbidity. Longitudinal population-based studies suggest that incidence and maintenance rates are both high, balanced by a high mortality ratio for those affected.

The aetiology of late-life depression remains unclear in some respects. While many population-based studies have been carried out in Europe and the USA, most of these have been cross-sectional in design, and have limited themselves to univariate analyses. The results of these investigations therefore appear as lists of cross-sectional associations, possibly confounded by other factors. While causal models can, and have been, inferred from such data, the process is fraught with difficulty and can lead to errors. More recently, good quality prospective studies have been carried out that have the potential to clarify the aetiology of these common disorders and inform primary and secondary prevention.

AGE

The data on the prevalence of major depression from the US Epidemiological Catchment Area (ECA) survey suggested a lower rate for those aged 65 (1.0%) than for those aged 45–64 (2.3%) and those aged 18–44 (3.4%)[3]. This relatively low prevalence rate among the older population was confirmed in a Canadian study using similar methodology[4]. These findings have been particularly controversial, as they could be taken to imply that the management of depression may require less resources per capita for the old than for the young[5]. They conflict with the general impression that the frequency of depressive symptoms and broader depressive syndromes either increases[6–8] or remains stable[9] with increasing age. The lay administered Diagnostic Interview Schedule (DIS) used to derive DSM-III diagnoses in the ECA excludes symptoms attributable to bereavement, physical illness or cognitive impairment. The ECA findings have been criticized on the grounds that the complex standardized symptoms, and the judgemental process required for responding to probes used in the DIS, may exceed the cognitive capacity of many older adults, leading to a systematic response bias. This may have been a particular problem where subjects were required to attribute symptoms to physical or non-physical causes. Older subjects report as many lifetime depressive symptoms as younger subjects, but are more likely to attribute them to physical causes, meaning that they are then excluded as a basis of diagnosing depression[10]. However a re-analysis of ECA data reattributing physical symptoms to psychiatric symptoms did not lead to a disproportionate rise in major depression among the older age groups[11].

A further curiosity has been the consistent finding that the lifetime prevalence of major depression seems to be lower for elderly subjects (1.4% for those aged 65 in the ECA survey) than for younger subjects (7.5% for those aged 30–44, from the same survey). It has been suggested that this may represent a cohort effect, with successive birth cohorts carrying an increasing propensity for major depression. More plausibly, this finding may have arisen from a selective tendency for older subjects not to recall earlier undiagnosed episodes[12] and from the selective mortality of those most vulnerable to repeated severe episodes of depression[8,13]. A broad review of this area reported similar findings for most psychiatric diagnoses, including schizophrenia, and concluded that cohort trends cannot be safely extrapolated from cross-sectional data[14].

GENDER AND MARITAL STATUS

One of the clearest and most reproducible findings in psychiatric epidemiology is the apparent excess of depression among women. It has been suggested that the extent of this excess varies across the life course, increasing from menarche into mid-life, and then declining gradually into late life[15]. The EURODEP consortium[16,17] reported a clear-cut excess of depression symptoms in older women in population-based studies from 13 out of 14 European centres. Interestingly, this association was consistently modified by marital status, with marriage being protective for men but a risk factor among women. Marriage is associated with relatively low mortality and good health, although this protective effect seems to be stronger for men than for women[18,19]. In younger people, marriage also protects against depression among men but not among women[20]. In Gove's[20] study, the excess of depression in women relative to men was greatest in married people. This striking finding has been variously attributed to the mundanity of housework and the unfavourable position of women who work outside the home[20] to the differences in the number and range of role identities by gender and marital status[21] and to the burden of childcaring[22]. Brown *et al*. drew attention to the lack of satisfaction with the married state expressed by

working class Camberwell women. In older people these observations are consistent with the observation from several studies that married older men cite their wife as their main confidante, whereas women more often cite a friend outside the home[24]. Also, in Finland, a prospective study showed that for men the risk of onset of depression over 5 years is increased for those having poor emotional relations with their wives, while for women the risk is greatest among those not living alone at the beginning of the follow-up period[25]. These findings led Kivels to suggest that marital counselling should be made available for older people. However, there may be external factors which, to the extent to which they affect wives and husbands and single men and single women differently, may have explained some of the observed gender/marital status interaction. One such factor may be the social integration and activity of single men and women. Never-married men reported fewer supportive friends and neighbours, less attendance at clubs or church, and more loneliness than never-married women in Gospel Oak[26,27]. Another area worthy of investigation is the relative health of male and female marital partners. A national US survey showed that 64% of all spousal carers were wives, suggesting that in older age the burden of care in marriages may generally derive from the husband and devolve on the wife[28].

DISABLEMENT

Of the world population, 7–10% are significantly affected by disablement, defined as the long-term consequences of chronic disease[29]. These estimates have varied little between world regions, and are similar for developed and developing countries[29]. There is, however, a strong positive relationship between disablement and age. The OPCS Surveys of Disability in Great Britain reported a near doubling of disability prevalence rates with each 10 year increase in age, from 7% for those aged 40–49, to 67% for those aged 80+[30]. Among older subjects, most detectable physical illness is chronic rather than acute[31].

Many studies have commented on the strength of the cross-sectional relationship between physical health variables and depression in older age. Gurland reviewed 70 years of research endeavour in this field, carried out in primary care, hospital and community settings, and concluded that there was strong accumulated evidence of a tendency for both physical illness and disability to co-exist with major and minor depression at a frequency greater than that expected by chance[32].

There have been suggestions from clinical populations of specific associations between late-life depression and diseases such as stroke[33] and Parkinson's disease[34]. Results from community surveys are less clear. However, stroke, respiratory disease and arthritis were all found to be associated by most studies which have assessed individual diagnoses[35–40], while hypertension and diabetes were less salient. This pattern of association with individual diseases would suggest that disablement, the limiting long-term consequences of disease, may be more relevant than any particular pathology. Indeed, the strongest reported associations have generally been between depression and summary measures of disablement. A systematic review of the literature, using MEDLINE for the period 1984–1996 and secondary references for earlier publications, revealed 10 cross-sectional studies which had used population samples[41]. They were consistent in reporting strong positive associations between disablement, measured in various ways, and depression[36–38,42–46]. However, the strong associations might not reflect a causal relationship. Bias (somatic contamination of the measurement of depression), confounding and, in particular, reverse causality (depression leading to disablement, rather than vice versa) were plausible alternative explanations. Later prospective population-based research has clarified the association. At least five longitudinal studies have now shown a very strong association between disablement at baseline and the subsequent onset of depression[47–51]. In the Gospel Oak survey[26,27], after adjusting for confounders, the most restricted quarter of the Gospel Oak population (London Handicap Scale) were 20 times more likely to be depressed at baseline than the least restricted quarter. Those among them who were not depressed at baseline were five times more likely than the least restricted quarter to have experienced an onset of depression at 1 year[50]. The population attributable fraction (the proportion of new cases that might notionally be prevented if the risk factor were removed) was 0.69. Most studies agree that it is the level of disablement associated with a health condition, rather than the nature of the pathology, that determines the risk for depression[50,52,53]. Three population-based studies have suggested an interaction between disablement and social support, with the strongest effect of disablement in those with the least social support[1,50,51]. Beekman *et al.*[1] reported that the association between disablement and depression was only apparent for minor rather than major depression. However, this finding was based upon cross-sectional research, and requires replication. Interestingly, in community studies, disablement does not seem to influence directly the process of recovery from late-life depression[50].

Ormel *et al.*[54] argue in a separate publication that synchronicity of changes in depression and disability observed longitudinally in a primary care-based study support the hypothesis that there is an important pathway leading from depression to disability. In reality, as most authors have acknowledged, the situation may be more complex; the causal direction may vary between individuals, and components of each direction may co-exist within the same individual. A case can also be made for reciprocal causation, with a physical impairment leading to handicap, provoking depression which may in turn exacerbate the degree of handicap associated with the original impairment.

LIFE EVENTS

The literature on life events in older people was recently reviewed[55]. In the main, two methods have been used. The Bedford College Life Events and Difficulties Schedule (LEDS)[56] elicits events in a lengthy semi-structured recorded interview. These are then rated independently for contextual threat by a trained panel. Studies using this detailed method have shown that depressed older subjects have experienced more recent life events than non-depressed subjects[57]. However, older samples differ from younger ones in that chronic difficulties are more prevalent than life events, and events typically carry relatively low levels of threat[58,59]. Also, in contrast with Brown's work on younger adults, health difficulties are an important source of adversity[57,58]. The second and more common approach has been to use a pre-determined checklist of events. In a community survey in the USA, the onset of illness affecting a subject or relative, the onset of money problems, and becoming a victim of crime were among the most common and most undesirable life events affecting subjects aged 55+[59]. Deaths of spouses, children and siblings were rated as highly undesirable, but were individually relatively infrequent. However, 14% of females and 12% of males experienced a family bereavement of some kind over 1 year. Most checklists focus on these event categories, with a particular bias towards bereavement and personal illness events. Evidence for a relationship between depression in older age and life events measured using checklists is generally weaker than in LEDS-based studies. Linn[64] found a small significant difference in the mean number of events experienced by depressed and non-depressed community subjects. Other studies have not replicated this finding[60–63]. In this study,

subjects' history of exposure to serious life events was ascertained retrospectively, at index assessment, over a period of up to 2 years prior to the time of interview. Perhaps for this reason, associations with prevalent depression at index assessment were more impressive than the prospective associations with the onset of depression 1 year later. It may be that the categories used by some life event checklists carry too little ''contextual threat'' to be relevant to the subsequent onset of depression. In the longitudinal Gospel Oak survey[20,27], at index assessment depressed subjects reported more life events, measured using a checklist of events likely to carry high contextual threat, than did non-depressed subjects. However, at follow-up only a weak non-significant trend towards an increased risk for the onset of depression was observed. Having something important lost or stolen was the only individual event associated with the onset of depression over 1 year.

SOCIAL SUPPORT AND THE BUFFER HYPOTHESIS

Brown demonstrated in a younger sample that negative self-esteem and lack of social support were vulnerability factors, increasing the risk of depression in the presence of a life event[23]. Murphy[57] reported a similar vulnerability for older subjects lacking a confiding relationship. Not all studies have replicated this finding. Murrell[61] found a direct protective relationship between self-esteem and depression, but noted that neither self-esteem nor health modified the association between life events and later depression scores. Social support has been infrequently investigated in older community samples, and the findings have not all been consistent. Murphy's finding of an association between a lack of confidants and depression was confirmed in New York[44]. Bowling reported a positive association between the number of confidants and well-being in a London sample, which was, however, not apparent in a sample drawn from a smaller town in Essex[65]. In both samples, health status accounted for more of the variance in well-being than did subjects' social support or social network characteristics. Bowling's finding of no association between social participation and well-being was contradicted by Palinkas' report, in a Californian study, of inverse associations between participation in church and other community organizations and depression[35,36]. Palinkas also reported an inverse relationship between social network size and depression. Both Palinkas[35,36] and Woo[66] in a study from Hong Kong[66], report inverse associations between the frequency of contacts with friends and depression. The Bowling, Woo and Palinkas studies all adjusted to some extent for subjects' physical health status, and Palinkas also controlled for age and gender. Each of these variables is a potential confounder of an association between social support and late-life depression. There are large differences between the social support networks of older men and women, women typically having more supportive and extensive networks of friends than men[35,36,67]. Palinkas hypothesized a deterioration of social network with increasing age consequent upon bereavement; he found an inverse association between age and network size in women, but not in men. Bowling[65] comments that active social engagement, such as visiting friends, is often confounded by functional ability, but unfortunately does not report her data on associations between social support or social network and health status. Palinkas found no association between physical health and social participation, or the number or frequency of social contacts[35,36], but other studies have observed disablement to be associated with smaller social networks[68,69].

One of the more consistent findings from the literature appears to be the salience to late-life depression of contact with friends, in particular intimate, confiding relationships. While older people typically receive instrumental support from spouses and relatives, they value friends for the companionship and emotional support that they can provide[70]. A review of recent research in the area concludes that interaction with friends, rather than frequency of contact with relations, is positively associated with emotional well-being[24]. This view was borne out in the longitudinal Gospel Oak study. No contact with friends was the only social support variable prospectively associated with the onset of depression[50]. In this study, lack of social support and social participation were more evidently associated with the maintenance rather than with the onset of depression.

SOCIAL CLASS, INCOME AND EDUCATION

Brown and Harris reported that working-class women with children at home were four times more likely to have experienced a depression than middle-class women[23]. Although they were more likely to experience life events, the class difference in depression was mediated more by the higher prevalence of four vulnerability factors among the working-class women. Murphy has reported a less dramatic social class effect in an older sample[57]. In her older subjects, the excess of depression among the lower social classes was largely explained by their poorer health and greater social difficulties. Social class, as measured by best pre-retirement occupation, may retain some validity after retirement, to the extent to which it relates to retirement income, housing quality, social network, and access to and use of formal services. There have been reports from cross-sectional community surveys from a variety of cultures of associations between late-life depression and relative disadvantage in income[37,38,44,66,71,72], housing status[37,38,66] and education[37,38,44,46,66,72]. These are, of course, highly correlated variables, and it will always be difficult to determine the effect of one independent of the others. The possibility of reverse causality also needs to be considered because of the well-recognized phenomenon of social drift; people whose adult life has been scarred by depression may experience occupational and economic disadvantage.

FAMILY HISTORY, GENETIC LIABILITY AND PAST PSYCHIATRIC HISTORY

The earliest evidence of a familial tendency in depression came from family studies in which the life-time prevalence of depressive disorder was compared between relatives of probands with depression and a control sample. Many such studies have been completed, with consistent results. Higher than expected rates of major depression and minor depression are found among relatives of probands with major depression, and higher rates of bipolar disorder and major depression among relatives of probands with bipolar disorder[73]. Such studies could only identify familial aggregation, and could not distinguish between familial similarity arising from shared environment or shared genes.

Early twin studies suggested a substantial contribution from both genes and shared environment[74]. Incorporation of environmental measures in genetically sensitive designs has advanced our understanding of the interplay between genetic and environmental risk factors for major depression. Kendler *et al.*[75] have completed extensive quantitative genetic analyses in a large cohort of same-sex (female) twins from the population-based Virginia Twin Registry. The heritability for a life-time diagnosis of major depression was 33–45%, depending on the diagnostic criteria that were applied. This estimate varied little between more and less restrictive criteria[75]. The heritability for 1 year prevalence of major depression also lay between 41% and 46%[76]. There was some suggestion that improving the reliability of the diagnosis of major depression might increase the estimates for the heritability

of the disorder, with up to half of the environmental contribution to the variance having reflected measurement error, leading to a dilution of the previous reported genetic contributions[77]. About 60% of the genetic effect contributed was indirect, mediated by past history of depression, neuroticism, life events and childhood adversity. Two coping strategies, turning to others and problem solving, which had been negatively correlated with levels of depression, were also found to have substantial heritability[78]. The relationship between genetic liability, stressful life events and depression was explored in detail, and evidence provided to support a gene–environment interaction in which genetic factors determined sensitivity to serious life events[79].

Data on older subjects is relatively lacking. Two studies from The Netherlands examined cross-sectional relationships between depression and the exposures of a family history of mental illness, and a personal past history of depression. In the Amstel study, based on a large population sample of 2540 subjects aged 65+, there was a positive association between a family history of mental problems and a diagnosis of GMS–AGECAT depression[80]. This association was modified by both cognitive status and personal past psychiatric history. The strongest association was seen in the group with a past psychiatric history and no cognitive impairment. However, only 22% of depressed subjects reported a family history of mental health problems, suggesting a modest population-attributable fraction. Van Ojen[13] also reported that, while depression was twice as common in those with a psychiatric history with an onset before the age of 65, the prevalence of this exposure decreased linearly with increasing age[13]. Only 22% of currently depressed subjects reported a previous episode of psychiatric illness with an onset before age 65. While failure of recall and "telescoping" of ages of onset might have accounted for these findings, the reduction in the prevalence of past history with increasing age was consistent with predictions based upon the known excess mortality among those so affected. The LASA study, based on a national Dutch sample of over 3000 subjects aged 65+, used two definitions of depressive disorder, major depression diagnosed using DIS, and minor depression defined as those scoring 16 or more on the Center for Epidemiological Studies Depression Scale. A family history of depression was associated with neither outcome. A past history of psychiatric disorder was strongly associated with major depression, with an odds ratio (OR) of 90.8 (39.1–211.1) and a population-attributable fraction (PAF) of 74%, but much more weakly associated with minor depression; OR 4.1 (2.3–7.3) PAF 7%.

COGNITIVE DECLINE

An inverse association between depression scores and cognitive test scores has been reported in four cross-sectional surveys[46,71,81,82] with one negative report[42]. These cross-sectional studies did not permit further analysis of direction of causality. However, at least one study has suggested that low mood may be a risk factor for subsequent decline in cognitive ability[83]. A biological basis for this association has been suggested; the failure, seen in chronically depressed subjects, of fast-feedback mechanisms to shut off the cortisol stress response may lead to high concentrations of neurotoxic metabolites, causing specific damage to hippocampal regions essential to new learning and memory recall tasks[84]. Alternatively, microvascular lesions leading to cognitive decline may also cause late-life depression through critical subcortical damage to frontotemporal cortical projections necessary for the maintenance of mood and motivation. MRI evidence suggests that first onsets of late-life depression may be associated with characteristic deep white matter lesions[85]. The finding from the Amstel study, that the associations between life events and depression and living alone and depression were not apparent in those with cognitive impairment, would be consistent with a hypothesis of an alternative pathway to late-life depression mediated through cerebral deterioration[86]. There may be a more prosaic explanation for a prospective association between cognitive decline and depression. Cognitive impairment, like other health impairments, may lead to depression to the extent to which it causes disability and handicap.

CONCLUSION

The factors most consistently implicated in these studies are similar to those observed in younger adults: constitutional or genetic vulnerability, e.g. a family history or past history of psychiatric disorder; current vulnerability, e.g. lack of social support, recent stress, as in life events, and current adversity, as in low socioeconomic class, poor housing or low income. However, some factors may be particularly salient for late-life depression, either because, as in the case of disablement or bereavement, they are a much more common exposure among the older population, or because they may impact differently upon those who are exposed, depending on their age. There is already evidence to suggest that disablement associated with declining health in older age may be a prime determinant of the prevalence, incidence and maintenance of late-life depression.

In younger adult populations, depression is a substantially heritable disorder in which both direct genetic effects and genetic effects mediated through childhood adversity, neurotic personality, coping styles, propensity for life events and sensitivity to life events can be discerned. Evidence from genetically sensitive designs in older populations is lacking, but circumstantial evidence suggests that the selective early death of those with an early first onset and multiple episodes of depression, who perhaps have a higher genetic loading for the disorder, may mean that the heritability of depression in late life is lower than in younger populations. The finding that the large majority of older depressed subjects are experiencing a first onset of the disorder raises the possibility of aetiological dissimilarity between early adult and late-life depression. There is a clear case for focusing in our investigations on those aspects of physical health status, cognition and social milieu that change most acutely in late-life and best distinguish the life experience of older and younger adults.

Risk Factors and the Incidence of Post-stroke Depression

P. W. Burvill

University of Western Australia, Australia

Post-stroke depression (PSD) is the most common psychiatric syndrome following stroke, but there is no specific PSD syndrome. It is commonly unrecognized and untreated in clinical practice. Rao[1] has reviewed the literature on the relationship between depression and cerebrovascular disease, including strokes.

PREVALENCE

Reported prevalence of PSD has varied between 30–60%, 8–30% major and 20–40% minor depression. The reasons for this wide variation include different assessment methods, diagnostic criteria, time elapsed after the stroke and patient settings, together with assessment difficulties in the presence of aphasic, cognitive and physical disabilities.

The lowest number of reported cases have come from community population-based studies. Several authors have concluded that it is unproved that depression is commoner in an unselected group of patients after strokes than it is among the elderly with other physical conditions. Most cases of PSD develop during the first 2–3 months post-stroke.

RISK FACTORS

Described pre-stroke risk factors include personal or family history of depression or other psychiatric disorder, socially impaired personality, neuroticism, high alcoholic intake, social isolation and negative life events. Post-stroke factors include perception of the effects of the stroke as a significant loss, dysphasia, significant disability, impaired cognition, living in a nursing home, isolation and poor social supports. Most, but not all, studies have reported age, gender, educational level and marital status as unimportant.

Described biological risk factors include pre-stroke subcortical atrophy, especially of periventricular white matter, site and size of the lesions, and ischaemic rather than haemorrhagic stroke.

Risk Factors and the Incidence of Post-stroke Depression

P. W. Burvill
University of Western Australia, Australia

Post-stroke depression (PSD) is the most common psychiatric syndrome following stroke, but there is no specific PSD syndrome. It is commonly unrecognized and untreated in clinical practice. Rao[1] has reviewed the literature on the relationship between depression and cerebrovascular disease, including strokes.

PREVALENCE

Reported prevalence of PSD has varied between 30–60%, 8–30% major and 20–40% minor depression. The reasons for this wide variation include different assessment methods, diagnostic criteria, time elapsed after the stroke and patient settings, together with assessment difficulties in the presence of aphasic, cognitive and physical disabilities.

The lowest number of reported cases have come from community population-based studies. Several authors have concluded that it is unproved that depression is commoner in an unselected group of patients after strokes than it is among the elderly with other physical conditions. Most cases of PSD develop during the first 2–3 months post-stroke.

RISK FACTORS

Described pre-stroke risk factors include personal or family history of depression or other psychiatric disorder, socially impaired personality, neuroticism, high alcoholic intake, social isolation and negative life events. Post-stroke factors include perception of the effects of the stroke as a significant loss, dysphasia, significant disability, impaired cognition, living in a nursing home, isolation and poor social supports. Most, but not all, studies have reported age, gender, educational level and marital status as unimportant.

Described biological risk factors include pre-stroke subcortical atrophy, especially of periventricular white matter, site and size of the lesions, and ischaemic rather than haemorrhagic stroke.

Disruption of adrenergic and serotonergic pathways by the lesion, giving depletion of biogenic amines, has been postulated.

Robinson and Starkstein[2] considered the location of the lesion in the brain as the single most important aetiological factor in PSD, with the highest frequency of PSD associated with anterior lesions in the left hemisphere. Their method of neuroradiological lesion location has been criticized[3]. Lesions of the globus pallidus, putamen and caudate nucleus in association with PSD have been described.

A recent literature review by Singh *et al.*[4] concluded that any definitive statements about stroke lesion location and risk of depression have not yet been substantiated. Anatomical correlates of PSD change over time and may explain interstudy differences in the association of lesion location with PSD[5]. Furthermore, mood changes may be mediated through the distant effects of lesions, as shown by PET studies, or the lesions may play a facilitatory role for another primary mechanism leading to depression. Many of these risk factors may be interrelated, e.g. size of lesions, disability, impaired cognition and living in a nursing home.

Epidemiology of Depression: Prevalence and Incidence

Dan G. Blazer

Duke University Medical Center, Durham, NC, USA

Many symptom checklists have been used to estimate the burden of depressive symptoms in community populations. The results of these studies are remarkably consistent, with the range of significant depressive symptoms estimated to be 10–25% (see Table 71.1). Estimates of the prevalence of major depression and dysthymic disorder are presented in Table 71.2 from four different countries. The prevalence of major depression is much lower in community samples than is the prevalence of depressive symptoms, 1–5% in most community surveys. Lower prevalences of major depression have been found in more rural samples with an estimate of less than 1% in a North Carolina rural sample, whereas urban studies have typically estimated higher prevalence. The prevalence of dysthymic disorder is generally higher than that for major depression, approximately 2–8%, depending on the instrument used in the survey. Prevalence estimates are difficult to compare cross-nationally, as different instruments are used. Comparison is even more difficult when symptom burden is confused with diagnosed cases. For example, if the prevalences of dysthymic disorder and major depression are combined and the frequent co-morbidity of dysthymic disorder and major depression taken into account, the majority of subjects suffering significant depressive symptoms in community populations still do not qualify for diagnosis. One of the major tasks facing psychiatric epidemiologists studying depression cross-nationally in the elderly is to explain the residual depressive symptoms in community samples not easily captured by the usual diagnostic categories.

In a recent review of 34 studies of the prevalence of late-life depression by Beekman *et al.*[11] (part of the EURODEP Study), the prevalence varied (0.4–35%). Arranged according to diagnostic category, major depression was relatively rare (weighted average prevalence of 1.8%), minor depression more common (weighted average prevalence of 9.8%) while all depressive syndromes deemed clinically relevant yield an average prevalence of 13.5%. Depression was more common among women and among older people living under adverse socioeconomic circumstances. In a cross-national comparison of nine European centers using the GMS–AGECAT package to abstract diagnoses, differences in prevalence by country were most evident, with a range from 8.8% in Iceland to 23.6% in Munich. The overall prevalence estimated by meta-analysis was 12.3%, 14.1% for women and 8.6% for men. Among the elderly, there was little variation by age across all sites.

The prevalence of depression in acute medical facilities is presented in Table 71.3. Estimates range from 5% to 10% for major depression but, of more importance, an additional 15–25% experience clinically significant symptoms not captured by the diagnosis of major depression. The same is true for estimates of prevalence in long-term care facilities (see Table 71.4). Estimates range between 5% and 15% for major depression, yet an additional 30% of the sample subjects (in one study) suffered clinically significant depressive symptoms that did not meet the criteria for major depression. Estimates of depressive symptoms and depressive diagnoses (major depression and dysthymic disorder) among the elderly should not be based solely on community samples. Older adults in hospital or residing in long-term care facilities are much more likely to

Table 71.2 Prevalence of dysthymia, minor depression and major depression in community samples of older adults

Author	Sample	(*n*)	Screening method	Findings
Blazer *et al.*, 1987[7]	Community sample in North Carolina, USA	1304	Diagnostic Interview Schedule (DIS)	0.8% with major depression, 2% with dysthymia, 4% with minor depression
Copeland *et al.*, 1987[8]	Community sample in Liverpool	1070	Geriatric Mental State Schedule	2.9% with major depression, 8.3% with minor depression
Beekman *et al.*, 1995[9]	Community sample in The Netherlands	3056	CES-D/DIS	2.0% with major depression, 12.9% with minor depression
Pahkala *et al.*, 1995[10]	Community sample in Finland	1086	DSM-III diagnosis	2.2% with major depression, 14.3% with minor depression

Table 71.3. Prevalence of depression in acute care medical facilities

Author	Sample	(*n*)	Diagnostic method	Findings
Koenig *et al.*, 1986[12]	VA inpatient sample of men 70+	171	Screening plus modified DIS	11.5% with major depression; 23% with significant depressive symptoms
O'Riordan *et al.*, 1989[13]	Acute medical geriatric assessment unit	111	Geriatric Depression Scale and Clinical Interview	4.5% with major depression; 3.6% with dysthymic disorder; 10.8% with significant depressive symptoms (most with dementia)

experience depressive symptoms and be diagnosed with major depression or dysthymic disorder than persons living in the community.

Incidence studies of depression in the elderly are extremely rare in the literature. Two studies provide some estimate of incidence, however. Rorsman *et al.*[18] estimated incident depression from the Lundby cohort in Sweden among 2612 individuals evaluated in 1957 and later in 1972 (i.e. 15 year incidence) until the age of 70. The cumulative probability of suffering a first episode of depression was 27% for men and 45% for women, a very high incidence figure in this cohort (especially compared to lifetime prevalence figures, reported in other studies, of less than 15%). The annual age-standardized first incidence for depression, all degrees of impairment included, was 0.43 for men and 0.76 for women. Incidence appears to decrease in the studies as individuals aged, especially for men. Eaton *et al.* (1997)[19] estimated the incidence of major depression over 10 years for the ECA cohort from Baltimore. They found an overall estimated annual incidence of 3.0 per 1000 per year, with a peak while subjects were in their 30s, a smaller peak when subjects were in their 50s and a definite lower incidence in the elderly. Prodromal symptoms were present many years before the full criteria for major depression were met, further linking the minor and major depression, Foster *et al.* (1991)[20] estimated the incidence of depression in long-term care facilities. In a cohort of 104 new admissions followed for a year, they found an incidence of 14%. One-third of these new cases were diagnosed as major depression, two-thirds as minor depression.

HISTORICAL TRENDS OF DEPRESSIVE DISORDERS

Historical studies in epidemiology assist investigators to establish the frequency of disorders in populations at different points in time. To understand the prevalence of major depression in late life compared to earlier stages of the life cycle in modern Western societies (e.g. major depression appears to be less frequent in older adults), an historical approach is necessary. Depressive disorders, such as tuberculosis, acquired immune deficiency syndrome (AIDS) and smallpox, wax and wane in frequency through time. Unfortunately, historical studies in psychiatric epidemiology are rare. Therefore, temporal changes in mental illness are difficult to determine.

Table 71.4. Prevalence of depression in long-term care facilities

Author	Sample	(*n*)	Diagnostic method	Findings
Parmelee *et al.*, 1989[14]	Nursing home and congregate apartment residence in Philadelphia	708	DSM-IIIR checklist	12.4% with major depression; 35% significant depressive symptoms
Bond *et al.*, 1989[15]	Three British NHS nursing homes	568	Critchton Royal Behavioral Scale and the Survey Psychiatric Assessment Scale	32–42% with severe affective disorder or psychoneurosis
Phillips and Henderson, 1991[16]	24 Australian nursing homes	323	DSM-IIIR criteria	6.1% of residents suffered from a severe depressive episode, 6.7% from a moderate depressive episode and 6.7% from a mild depressive episode
Gerety *et al.*, 1994[17]	5 Nursing homes	135	Structured Clinical Interview for DSM-III-R diagnoses	26% diagnosed with a major depressive episode

Some investigators, however, have explored historical trends via the so-called "cohort effect". Klerman[21] noted that, in contrast to the "age of anxiety" following the Second World War, modern Western society may be entering an "age of melancholy", precipitated by social factors, such as the threat of nuclear warfare, a perceived threat of environmental pollution and economic instability. Estimates of prevalence by age from the Epidemiologic Catchment Area Studies in the USA reveal a significant decrease in both current and lifetime prevalence of major depression by age cross-sectionally. In a separate study, Klerman *et al.*[22], analyzing family history data from subjects in the Psychobiology of Depression Study, found a progressive increase in the rates of depression in successively younger birth cohorts throughout the twentieth century, with an earlier age of onset of depression with each successive birth cohort. However, these cross-sectional studies, which suggest an "age of melancholy", must be considered in the context of historical studies.

To interpret historical trends, one must consider the cohort effect. Four findings suggest that younger birth cohorts carry a higher prevalence of depression than older cohorts. First, longitudinal studies have typically demonstrated a consistent burden of depression across the life cycle for each birth cohort[23]. That is, the prevalence of depression within a birth cohort does not change with increasing age. Second, younger birth cohorts appear to experience higher prevalences of depression than the older birth cohorts in the latter two decades of the twentieth century[24,25]. Third, suicide rates do increase with age, which in turn drives the overall rate of suicide up with age[26]. Fourth, the changes in rates of suicide and depression by age group over the past 50 years have been of such magnitude that the varying rates are best explained by psychosocial rather than biological or evolutionary factors.

Those factors that contributed to a relative protection of older birth cohorts from depression and suicide in the 1990s in Western societies, compared to younger cohorts, and that contributed to the relative increase in depression and suicide among younger cohorts in the 1990s, are unknown (but subject to much speculation). Interpreting these data, investigators and clinicians must take care to recognize that significant methodological problems in historical studies remain. Even a clear and decisive endpoint, such as suicide, can be misleading, for suicide rates are obtained from a review of death certificates, which are subject to considerable bias. Methods for estimating the prevalence of depression change through time, and therefore it is difficult to compare studies from many years in the past with current studies (due to an evolving instrumentation for measuring depression in community and clinical samples).

CONCLUSION

In summary, it appears that results from cross-sectional studies in Western societies estimate the prevalence of depression in older adults to be lower than the prevalence in young and middle-aged adults. These findings are most striking in the USA (particularly the Epidemiologic Catchment Area Studies) but also appear in other studies. Nevertheless, these findings must be interpreted with caution. Methodological problems in identifying depression across the life cycle may contribute to these difficulties. In addition, birth cohorts, with the well-known stability of function and disease that birth cohorts demonstrate, must be taken into account before cross-sectional data are translated into longitudinal interpretations.

Epidemiological Catchment Area Studies of Mood Disorders

Dan G. Blazer

Duke University Medical Center, Durham, MC, USA

The National Institute of Mental Health Multi-site Epidemiologic Catchment Area (ECA)[1] Program consists of a combined community and institutional survey of five communities in the USA: New Haven, Connecticut; Baltimore, Maryland; Durham, North Carolina; St Louis, Missouri and Los Angeles, California. Because of the large sample drawn for this study and because oversamples of the elderly were drawn at three sites, data are available that permit the estimate of the prevalence of affective disorders from a larger sample of community-dwelling elders than from any other extant study.

The goals of the Epidemiologic Catchment Area Program were to: (a) estimate the prevalence of specific psychiatric disorders using a similar methodology across multiple geographic sampling areas; (b) determine correlates of these specific psychiatric disorders; and (c) determine the relationship between psychiatric disorders and health services utilization.

The 6-month prevalence of the affective disorders from the five ECA sites overall range from 4% to 7%[2]. All affective disorders, except for bereavement, were less prevalent in the elderly than at other stages of the life cycle. For example, the prevalence of major depression in men ranged between 1% and 4% among the 18–24 year-olds but was consistently less than 1% in the 65 age group. Among 18–24 year-old women, the prevalence of major depression was 7%, whereas in women in the 65+ age group it did not exceed 3% at any of the ECA sites. Recent incidence studies from the ECA sample suggest that the incidence for major depression peaks in the 30s with a smaller peak during the 50s. Incidence is much lower for the elderly.

Dysthymic disorder varied less by age in prevalence than major depression and was more prevalent than major depression in the elderly[3]. For example, the prevalence of dysthymic disorder was 0.5–3% in 18–24 year-old men and 0.5–2% in 65 year-old men. Among women, dysthymic disorder was 1–4% in 18–24 year-old women and between 1–4% in 65+ year-old women. Overall, current affective disorders of all types were less frequent in older persons (65+ years of age) than for any other age group. Manic disorders were extremely rare in the sample overall (0.5–1%). No cases of mania were identified in the 65+ age group across the five ECA sites.

The lifetime prevalence rates for the DSM-III specific psychiatric disorders evaluated in the ECA sample paralleled rates of current prevalence but, as would be expected, were higher[3]. Lifetime prevalence for major depression was 4–10% in the 25–44 age group but was not higher than 2% in the 65+ age group at any ECA site. Only one lifetime occurrence of manic episode was identified in this very large sample.

The ECA studies have received considerable criticism from geriatric psychiatrists who perceive that the study design significantly underestimates the prevalence of affective disorders in older adults. The dramatic differences in prevalence (both current and lifetime) by age surely calls for some explanation. Studies are emerging to suggest that the Diagnostic Interview Schedule, the instrument used to determine the prevalence of psychiatric disorders in the ECA sample, may possibly be biased toward underestimating the prevalence of affective disorders in older persons. Specifically, the threshold for a symptom being identified by the instrument may be increased for older persons. Nevertheless, the threshold effect does not appear to explain the dramatic differences in prevalence and has led a number of investigators to suspect that a cohort phenomenon is operative[5]. That is, older persons not only have lower current prevalence of depression in the 1990s, they have always experienced a lower prevalence. According to a number of studies, this is true among more modern, Western societies.

EURODEP—Prevalence of Depression in Europe

John R. M. Copeland

Royal Liverpool University Hospital, Liverpool, UK

The aims of the EURODEP Concerted Action were to use existing studies which had employed the GMS–AGECAT method of diagnosis to assess the prevalence of depression in nine European countries (10 centres)—Liverpool, Amsterdam (sample A), Berlin, Dublin, Iceland, London, Maastricht, Munich, Verona and Zaragoza. Later Tirana was added (not reported here), and five non-AGECAT centres joined after the study commenced—Bordeaux, Oulu, Antwerp, Amsterdam (sample B) and Göteborg.

All subjects were aged 65 or over. In Munich the subjects were aged 85 and above and in Iceland 85–87. The Amsterdam study (sample A) had an upper age limit of 84. All the studies took random samples in the community except Dublin, which sampled a general practice. Sample size varied from 202 in Verona to 5222 in Liverpool, giving a total sample of 13 803. Substantial differences in the prevalence of depression were found, with Iceland having the lowest level at 8.8%, followed by Liverpool, 10.0%; Zaragoza, 10.7%; Dublin, 11.9%; Amsterdam, 12.0%; Berlin, 16.5%; London, 17.3%; Verona, 18.3%; and Munich, 23.6%. When all five AGECAT depression levels, including both subcases of depression and cases, were added together, five high-scoring centres emerged, namely Amsterdam, Berlin, Munich, London and Verona (30.4–37.9%) and four low-scoring centres, Dublin, Iceland, Liverpool and Zaragoza (17.7–21.4%). There was no constant association between prevalence and age. A meta-analysis of the pooled data on the nine European centres yielded an overall prevalence of 12.3% (95% CI, 11.8–12.9); for women, 14.1% (95% CI, 13.5–14.8) and for men, 8.6% (95% CI, 7.9–9.3%)[1].

The proportions of depressive symptoms were found to vary between centres. In Amsterdam, for example, 40% of a general population of older people admitted to depressive mood, compared to only 26% in Zaragoza. Symptoms such as "future bleak", "hopelessness", "wish to be dead", were generally rare, but the last reached higher levels in Berlin, Munich and Verona. Sleep disturbance was admitted by only 15% of the population in Dublin, but 54% and 60% in Munich and Berlin. Large differences for some depressive symptoms were found within the very old populations, with lower levels in Iceland and higher levels in Munich. Overall, the levels of depressive symptoms among over 60% of the older general population of Europe were low, so that pejorative stereotypes of old age in Europe were not upheld[2].

In order to include non-AGECAT centres, attempts were made to harmonize the depression measures that had been used with items from the Geriatric Mental State examination. A scale was constructed, the Euro-D scale[3]. The scale appeared to work well and was applied to data from 21 724 subjects. Euro-D scores tended to increase with increasing age, unlike the levels of prevalence of depression. Women had generally higher scores than men, and widowed and separated subjects higher than those who were currently or never married[4].

Depression was confirmed as a common illness among older people in Europe. A number of other studies have shown poor treatment levels. It was concluded that opportunities for effective treatment were almost certainly being lost.

Depression in Older Primary Care Patients: Diagnosis and Course

Jeffrey M. Lyness and Eric D. Caine

University of Rochester Medical Center, Rochester, NY, USA

Depressive symptoms and syndromes in later life are a major public health problem[1,2]. Primary care clinical settings are especially important venues to better understand depressive psychopathology among older people. Older people with psychiatric disorders utilize mental health services infrequently, especially in comparison with younger persons, yet they are *more* likely to see their primary care physicians regularly[3,4]. Elders who complete suicide have often seen their primary care providers shortly before death, and the majority of them were suffering from depressive conditions at the time of their death[4]. There are also many lines of evidence suggesting that the nature of psychopathology seen in primary care differs from that seen in

In Amsterdam, for example, 40% of a general population of older people admitted to depressive mood, compared to only 26% in Zaragoza. Symptoms such as "future bleak", "hopelessness", "wish to be dead", were generally rare, but the last reached higher levels in Berlin, Munich and Verona. Sleep disturbance was admitted by only 15% of the population in Dublin, but 54% and 60% in Munich and Berlin. Large differences for some depressive symptoms were found within the very old populations, with lower levels in Iceland and higher levels in Munich. Overall, the levels of depressive symptoms among over 60% of the older general population of Europe were low, so that pejorative stereotypes of old age in Europe were not upheld[2].

In order to include non-AGECAT centres, attempts were made to harmonize the depression measures that had been used with items from the Geriatric Mental State examination. A scale was constructed, the Euro-D scale[3]. The scale appeared to work well and was applied to data from 21 724 subjects. Euro-D scores tended to increase with increasing age, unlike the levels of prevalence of depression. Women had generally higher scores than men, and widowed and separated subjects higher than those who were currently or never married[4].

Depression was confirmed as a common illness among older people in Europe. A number of other studies have shown poor treatment levels. It was concluded that opportunities for effective treatment were almost certainly being lost.

Depression in Older Primary Care Patients: Diagnosis and Course

Jeffrey M. Lyness and Eric D. Caine
University of Rochester Medical Center, Rochester, NY, USA

Depressive symptoms and syndromes in later life are a major public health problem[1,2]. Primary care clinical settings are especially important venues to better understand depressive psychopathology among older people. Older people with psychiatric disorders utilize mental health services infrequently, especially in comparison with younger persons, yet they are *more* likely to see their primary care physicians regularly[3,4]. Elders who complete suicide have often seen their primary care providers shortly before death, and the majority of them were suffering from depressive conditions at the time of their death[4]. There are also many lines of evidence suggesting that the nature of psychopathology seen in primary care differs from that seen in

psychiatric or residential care sites[3,4,6,7]. Thus, to better understand the nature of depression seen among primary care elders, we must study subjects recruited from primary care practices[8–11].

A growing number of studies have examined the prevalence of mood disorders among older primary care patients. Similar to younger and mixed-age primary care samples, major depression is common, with a point prevalence of 5–10% in the elderly[6,12,13]. An even greater number of patients have a history of major depression but are currently not fully syndromic, i.e. the point prevalence of major depression in partial or full remission is approximately 12%. Thus, one-fifth of all older persons seen in primary care settings have a depressive condition that, at the least, requires vigilance and education regarding recurrence and may require acute, continuation or maintenance therapy.

The prevalence of so-called "lesser" depressive conditions is also considerable among primary care elders. Dysthymic disorder is relatively uncommon, however, with an estimated point prevalence of 1%, of which half is co-morbid with superimposed major depression[6]. This low prevalence primarily reflects that the specific entry criterion of dysthymia seems to be less applicable to elders, where they fail to fulfill the requirement that depressed mood occurs for "most of the day, for more days than not . . . for at least two years". However, studies using any of various definitions of "minor", "subsyndromal" or "subthreshold" depression have noted point prevalences comparable to those for major depression[7,14,15]. For example, one study used the criteria set for minor depressive disorder proposed in the Appendix to DSM-IV, finding a prevalence of 5%[7]. The same group also arbitrarily defined a subsyndromal group comprising patients scoring >10 on the Hamilton Rating Scale for Depression (but *not* meeting criteria for major or minor depression) and noted a point prevalence of 10%. Some have raised concerns that classifying such "lesser" depressive symptoms as mood disorder is bringing "normal" age-related distress under the rubric of psychopathology. In fact, patients with minor and subsyndromal depression suffer both medical co-morbidity and functional disability comparable to that of major depression (and substantially greater than non-depressed controls), suggesting that these are conditions of considerable clinical importance, albeit a heterogeneous and as-yet poorly characterized group.

While studies of younger or mixed-age groups of primary care patients have demonstrated that major depression has high rates of persistence in both remitting–recurring and continuous patterns, broadly comparable to the chronicity seen in psychiatric treatment settings, much less is known about elders. So-called "lesser depressive symptoms" were powerful risk factors for subsequent new onset, or recurrent, diagnosable depression disorders in mixed-age or younger adults[16,17]. However, few investigations have focused on older persons or disentangled the findings of their older subjects from their younger subjects. Two prospective studies[18,19] of older depressed subjects found that depressive symptoms (at 33 months and 9 months, respectively) had considerable rates of persistence but also of remission and recurrence. Both studies assessed depression solely by use of self-report depressive symptom scales, and therefore were unable to determine specific depressive diagnoses. These results were also limited by the potentially reduced validity of self-report methodology regarding depressive symptoms among older persons. One recent report[12], using well-operationalized measures to establish a research diagnosis of major depression among older patients seen at university-affiliated internal medicine centers, found that at 6 month follow-up 38% of subjects with major depression continued to be fully syndromic, and only 11.5% were fully recovered. Preliminary data from our group showed that more than half of older primary care patients suffering major, minor or subsyndromal depression still suffered clinically significant depressive symptoms at 1 year (Lyness *et al*., manuscript in preparation). In sum, the course of major and other depressions among primary care elders is largely unknown, but available evidence suggests considerable persistence, as well as variability of symptoms, over time.

Similarly, examination of specific predictors of outcome in this group is largely lacking. Medical illness burden is the most powerfully and consistently identified factor associated with the presence or course of depression in later life[1,20,21]. However, most studies of the relationship of medical illness to depression in later life have used psychiatric patient populations or mixed-community samples, rather than subjects from primary care settings. There have been cross-sectional studies demonstrating an association between medical illness burden and depression in primary care elderly[6,12,22]. Two published longitudinal investigations of older primary care patients[18,19] found that medical status (number of illnesses and self-health perception, respectively) predicted depressive symptoms at 33 and 9 month follow-up, respectively. However, these studies were limited by the use of relatively crude proxies for medical co-morbidity and by a lack of diagnostic assessments for depression. Thus, the predictive role of medical illness (measured by validated instruments) with regard to major or subsyndromal depression in primary care elderly remains to be defined. Similarly, other factors that predict depression outcome in younger adults, or in older psychiatric or nursing-home patients, include functional disability, personality trait neuroticism and social support; with few exceptions, these predictors have not been studied in primary care elders.

Little is known about treatment, too. In our above-cited study, less than half of patients with current major depression were prescribed antidepressant treatment[7], consistent with findings in younger people that depression is frequently undertreated. A wide variety of physician, patient and physician–patient interaction factors may underlie this low treatment rate, but these remain to be defined rigorously through a variety of quantitative and qualitative study methods. Also, antidepressant treatment rates were similar for major, minor and subsyndromal depression groups, despite the lack of empirical support for medication efficacy for the latter conditions. This suggests that the primary care physicians did not discriminate among these diagnostic categories. Rather, they appear to make treatment decisions based on factors that do not directly relate to the symptomatic or syndromic severity of their patients' depressive conditions.

Neurochemistry

L. S. Schneider, updated by M. T. Abou-Saleh[1]
St George's Hospital Medical School, London, UK

As a preface to this chapter, it is important to consider that major depression is characterized and defined by descriptive, not biological, criteria, making it unlikely that a neurochemical finding could adequately characterize the disorder. The underlying validity of the diagnosis is assessed against other descriptive features of the illness such as symptoms, course, treatment outcome and biological changes. Yet people who manifest similar clinical phenomenology may not necessarily share similar pathophysiology. Major depression is heterogeneous in its expression, possessing various phenomenology, family history and course. Therefore, the underlying biology of each subtype would be expected to be distinct from others. This, however, is often not the case.

In the elderly, a neurochemical characteristic of depression would have to be sufficiently specific to distinguish depression from dementia or from secondary depression. In addition, neurochemical differences would be expected between late-onset and early-onset depression, or delusional and non-delusional depression, thus helping to validate these putative subtypes.

PRIMARY DEMENTIA VS. PRIMARY DEPRESSION IN THE ELDERLY

Both of these disorders share certain neurochemical characteristics and behavioural symptoms. For example, noradrenergic deficits are common to both disorders. Interestingly, greater neuronal loss in the nucleus locus coeruleus, the main noradrenergic outflow to the cortex, occurred in Alzheimer's disease (AD) patients who showed clinical manifestations of depression before death than in those who did not[1,2]. Similarly, primary dementia patients with major depression had over a 10-fold greater reduction in norepinephrine (noradrenaline) than non-depressed dementia patients[3], suggesting that, at least among elderly patients, noradrenergic functions may play a role in secondary depression.

Cerebrospinal fluid (CSF) studies demonstrate decreased concentrations of somatostatin in both major depression and AD patients, often with no differences in monoamine metabolites[4].

SECONDARY VS. PRIMARY DEPRESSION

Significant depressive symptomatology is common in older groups, who are more likely to be medically ill, and depressive symptoms in medically ill patients range from 10% to 50%[5]. However, the neurochemistry associated with depression in the elderly, such as the dexamethasone suppression test (DST), thyroid releasing hormone (TRH) test and platelet monoamine oxidase (MAO) activity, as discussed below, may change in physical disease as well as in depression, so that their adequate evaluation requires consideration of the effects of medical illness[6–8].

LATE-ONSET VS. EARLY-ONSET DEPRESSION

Early-onset depressives, i.e. patients with depression first occurring earlier in life, may be biologically distinguished from similarly-aged patients with late-onset depression. For example, late-onset elderly patients have a lower sedation threshold to amobarbital (both before and after treatment) than early-onset depressives[9]; they may have greater corticol atrophy and ventricular enlargement; and they may have relatively increased platelet MAO activity (see below).

DELUSIONAL VS. NON-DELUSIONAL DEPRESSION

Delusional depression may represent a distinct clinical subgroup and be more common among patients with late-onset depression[10]. Yet there is little evidence for biological differences between groups of depressed patients with and without delusions. For example, urinary MGPG (3-methoxy-4-hydroxy-phenylglycol), a metabolite of norepinephrine, has been reported to be reduced[11], increased[12] and not different[13] in delusionally depressed patients. Similarly, serum levels of dopamine-β-hydro-oxylase have been reported to be both lower[14] and not different[15] in delusional depression.

BIOLOGICAL CHANGES IN AGING AND DEPRESSION

Many of the neurobiological changes associated with aging are similar to those that occur with depression. For example, normal aging and depression are both associated with decreased brain concentrations of serotonin, dopamine, norepinephrine, their metabolites, increased brain MAO-B activity, increased hypothalamic–pituitary–adrenal (HPA) activity and increased sympathetic nervous system activity[16].

Principles and Practice of Geriatric Psychiatry, 2nd edn. Edited by J. R. M. Copeland, M. T. Abou-Saleh and D. G. Blazer

HYPOTHALAMIC–PITUITARY–ADRENAL (HPA) AXIS

Depression across the age range is associated with hyperactivity and dysregulation of the HPA axis, characterized, in part, by elevated plasma and urinary cortisol, increased corticotropin-releasing hormone (CRH), blunted corticotropin (ACTH) response to CRH and resistance of cortisol to suppression by dexamethasone. Increased cortisol secretion is probably the most consistently observed physiological abnormality in patients with major depression (see Chapter 81 on dexamethasone suppression test).

Total urinary free cortisol may reliably distinguish depressed from non-depressed individuals in clinical studies of mixed-aged adults. The levels of cortisol, furthermore, appear to correlate with the severity of depression, the presence of psychotic features, and with cognitive impairment[17]. Anatomical imaging research shows correlations of cortisol with brain ventricular enlargement[18].

One way in which aging and depression may interact is as follows. It is possible that normal aging is associated with enhanced limbic–hypothalamic–pituitary–adrenal axis activity, possibly due to age-associated neuronal degeneration in the hippocampus. The neuronal degeneration, in turn, may result from increased levels of glucocorticoids associated with both depression and aging. Depressive illness in the elderly may exacerbate this condition, as may repetitive stressful life events.

PLATELET MONOAMINE OXIDASE (MAO) ACTIVITY

MAO catalyses the oxidative deamination of several monoamines and exists in two forms, identified by relative substrate specificity. In the brain, both MAO-A and MAO-B are present; in platelets, only MAO-B is present. In the brain, MAO-B may be more responsible for the degradation of dopamine and MAO-A for norepinephrine.

Platelet MAO activity increases with age, nearly doubles between ages 30 and 80, and is higher in females than males[19]. Platelet and brain MAO-B activity is increased in AD, over and above the increase associated with age[20,21]. Some medical conditions, including liver disease, anaemia, epilepsy and cancer, are also associated with increased MAO activity, whereas in diabetes this may be lower[7]. Although not specific for a particular psychiatric disorder, differences in platelet MAO activity seem to distinguish certain depression populations. Among subgroups of mixed-age, depressed subjects, MAO activity has been reported to be higher in primary depressed, non medically-ill outpatients than in controls, and also higher in secondary than in primary depression[22,23]. MAO activity may not distinguish endogenous from non-endogenous or delusional from non-delusional depression[22], but it may be lower in bipolar compared with unipolar depression[24].

Post mortem studies of MAO in the brain have shown that the quantitative distribution of MAO-A in brainstem monoamine nuclei is normal in major depression[25]. However the density of brain MAO-B in suicide victims showed a positive correlation with age, but was not different between suicides and age-matched controls[26].

Elderly female inpatients with primary, unipolar depression, predominately endogenous, whose illness onset was in mid-life, may have lower platelet MAO activity than either later-age-onset depressed females of controls[27], suggesting that despite similar clinical presentation, decreased MAO activity may be associated with early-onset depression in the elderly. On the other hand, in elderly depressed female outpatients, MAO activity was higher than controls, but age of onset was not assessed[28]. In a depressed population, lower platelet MAO activity predicted the occurrence of neurotic depression (ICD-9) 10 years later[29].

In a group of elderly, depressed outpatients, higher platelet MAO activity was correlated with anhedonia, anxiety, a positive family history of depression and response to MAO inhibitors[30]. Depressed patients with reversible cognitive impairment have higher MAO activity than depressed patients without cognitive impairment[31]. Also, among elderly outpatients, MAO activity was increased in a group with depression secondary to mental illness compared with a primary depression group[32]. Thus, changes in platelet MAO activity are complex among the elderly depressed population.

Platelet MAO activity may serve as a vulnerability marker for pyschopathology in general. Association studies suggested that in the population with age over 40 years, presence of the 165 bp allele of DXS7 at the MAO locus was significantly associated with unipolar depression[33]. Both high- and low-MAO activity are associated with increased risk of bipolar disorder, depression and alcoholism in family members.

SEROTONIN

Deficits in the serotonin neurotransmitter system have been implicated both in major depression and in suicide. Numerous studies have demonstrated an association between low platelet 5-HT uptake and depression and a recent study showed higher uptake efficiency in depressed patients with high net uptake rate but similar 5-HT content to normal controls[34]. Many studies suggest that the serotonin metabolite 5-hydroxyindole acetic acid (5-HIAA) is decreased in the CSF of depressed patients; presynaptic serotonin function is decreased as well[35]. Specific brain ^{3}H-imipramine binding sites are correlated with serotonin patterns of innervation and are located on presynaptic serotonergic nerve terminals[36]. The active component for this binding site has a role in modulating neuronal serotonin uptake. Among suicide victims, at least, there is evidence for a decrease in the number of imipramine receptors[35], and an increase in the number of postsynaptic serotonin$_2$ receptors[37]. This latter finding may represent upregulation due to decreased intrasynaptic serotonin.

The role of 5-HT has also been investigated in genetic, neuroimaging, neuroendocrine and post mortem studies. Serotonin transporter gene polymorphism was not associated with old-age depression[38]. However, in patients with Parkinson's disease, those with the short allele of the 5-HT transporter promoter region—associated with low 5-HT transporter density—had higher depression and anxiety scores than those without this polymorphism[39]. Secondary depression to Parkinson's disease, stroke and Huntington's disease in the elderly is associated with low cerebral blood flow and metabolic rate in orbital frontal cortex and basal ganglia, suggesting that, as in primary depression, there is disruption in cortical–basal ganglia–thalamic neuronal loops[40], abnormalities that are under 5-HT control[41]. Poststroke depression is associated with blunted prolactin response to buspirone indicating low 5-HT activity[42]. Serotonin transporter density, measured using paroxetine binding in midbrains of suicides with major depression, were comparable to values obtained in normal controls[43].

Although a considerable literature evaluating CSF markers in mixed-age depressed and suicidal patients exists, only one study has focused specifically on elderly depressed subjects. In this study, both CSF 5-HIAA and the dopamine metabolite homovanillic acid (HVA) were lower in elderly depressed patients who attempted suicide than in depressed non-suicidal patients and controls[44].

PLATELET ^{3}H-IMIPRAMINE BINDING

The ^{3}H-imipramine binding site is found in brain and on platelets, the two sites sharing many characteristics with each other. The binding site is closely related to the presynaptic serotonin-uptake site. Thus, during the last decade, platelet ^{3}H-imipramine binding density (β_{max}) has been examined extensively as a biological marker for mood disorder. Approximately two-thirds of the studies have reported β_{max} among certain depressive subtypes[46,47], including those with a family history of depression[47,48]. However, β_{max}values seem also to be decreased in obsessive–compulsive disorder, anorexia and enuresis. ^{3}H-imipramine binding defined by desmethylimipramine was lower in the putamen of non-violent depressed suicides and those who were antidepressants-treated than normal controls[49].

The effect of age on platelet binding density has not been systematically investigated. A few studies suggest an increase, decrease, or no change in density with age, but the age ranges have been limited. Animal studies suggest that brain binding sites increase with age[36]. Elderly unipolar depressed patients also show a 20–42% decrease in binding density when compared to age-appropriate controls, although, again, this is not always so[50].

Differences among specific depression subtypes in the elderly have not been widely studied; platelet receptor density seems to be somewhat lower in elderly depressed patients compared to a younger depressed cohort[51]. Platelet ^{3}H-imipramine β_{max} may discriminate between depression secondary to medical illness and primary major depression, with density decreased in primary depression patients compared to secondary depression patients and controls[32].

It is not known whether this marker represents a trait or a state characteristic. The evidence suggesting state dependence is that depressed patients treated with electroconvulsive therapy showed an increase in binding density[52]. The administration of various medications such as fluoxetine, paroxetine, citalopram and chlorimipramine affect imipramine binding.

Platelet ^{3}H-imipramine binding density does not seem to be affected, overall, in groups of AD patients[51,53,54] compared to controls, but AD patients with agitation and delusions may have a lower density than AD patients without these symptoms[53].

NORADRENERGIC FUNCTION

Studies in depression have failed to demonstrate consistent differences in brain of CSF norepinephrine (NE) or MHPG levels. Normal aging is associated with a decrease in brain NE and a loss of neurons from the noradrenergic nucleus locus coeruleus. In addition, there are decreases in two enzymes required for norepinephrine synthesis, tyrosine hydroxylase and dopa decarboxylase. A post mortem study of depressed patients reported lower NE transporter binding of ^{3}H-nisoextine in the midcaudal portion of the locus coeruleus (LC) than normal controls, which may be related to low NE availability[55]. Tyrosine hydroxylase (TH) immunoreactivity is reduced in LC in depressed non-suicidal patients indicating low NE availability[56], whilst its expression is elevated in LC of depressed patients indicating premortem overactivity or deficiency in NE[57]. Neurotrophin 3 which was shown to prevent the death of central NE neurons is low in CSF of elderly patients with major depression[58].

Platelet α_2-Adrenergic Binding

Presynaptic α_2-receptors, in general, seem to function as noradrenergic modulators by regulating NE through a feedback mechanism. Activation of the receptor decreases NE function, while antagonism increases it. Decreased α_2-receptor density in brain and platelets may indicate a subsensitive autoreceptor system with increased NE activity, whereas increased α_2-autoreceptor density may be a characteristic of the putative deficits in central NE function in depression. However, a post mortem study of α_2-receptor activity in prefrontal cortex and hippocampal cortex in depressed patients showed similar levels to values in normal controls[59].

α_2-Adrenergic receptors exist peripherally on platelets, and in most studies, appear increased in depressed patients[60]. Increased platelet α_2-receptors have also been found in elderly depressed compared to age-appropriate controls[61] (studies that report increased α_2-receptors tend to use α_2-agonists in the assay while studies showing no difference tend to use antagonists).

CONCLUSION AND METHODOLOGICAL LIMITATIONS

Limited work has been done in specifically assessing the neurochemistry of depression in the elderly. The biological characteristics discussed here generally discriminate depressed from non-depressed in older as well as in younger groups, but often occur in other disorders as well. Therefore, neurochemistry characterizing depression in the elderly has limited generalizability and validity.

Some of the neurochemical findings described may not be specific to affective disorder in the elderly, but indicate traits that are over represented in groups of depressed patients when compared to the general population. For example, decreased platelet imipramine binding density may characterize people with relative serotonin system deficits, who may be at increased risk for depression, or who have symptoms related to depression. Or, increased platelet α_2-receptor binding may identify individuals who possess noradrenergic or arousal defects associated with depression.

Whereas platelet, plasma and CSF are sources of assayable human tissue, the relationship of their biochemistry is not well understood. The similar embryological origin of megakaryocytes and neurons has been used to justify or explain platelet research findings. However, these cells and their platelets have differentiated considerably from neurons and are exposed to significantly different physiological influences. Thus, it could be considered remarkable that it is possible to use platelets at all in the manner discussed here.

The majority of these studies are based on cross-sectional assessments during an acute phase of illness, or at death. Longitudinal studies are needed to assess test–retest reliability, state vs. trait and other characteristics. An adequate understanding of the neurochemistry of depression in the elderly must address age effects and the effects of depression subtypes, and must adequately explain how the neurochemistry is related to the depression.

Neuro-imaging

Neuro-imaging Studies of Depression

Mohammed T. Abou-Saleh
St George's Hospital Medical School, London, UK

The use of neuro-imaging techniques in the study of depression has provided a major advance in the elucidation of its functional neuro-anatomy, metabolic correlates and biochemistry. Structural neuro-imaging techniques, such as computed axial tomography (CT) and magnetic resonance imaging (MRI) have demonstrated an association between structural brain abnormalities and depression in patients with unipolar and bipolar disorder[1]. Whilst these abnormalities are non-specific, there is evidence that volume reduction in the caudate[2] and frontal lobe[3] are specific abnormalities in depression, particularly in late-life depression. MRI studies have consistently shown an increase in the number and/or severity of signal hyperintensities in the white matter in both unipolar and bipolar disorder[4]. Deep white matter lesions have been shown in elderly patients with unipolar depression predominantly in the frontal lobes and basal ganglia, supporting the notion of frontostriatal dysfunction in depression. These lesions have been shown to be associated with poor long-term outcome[5]. A recent population-based study of over 1000 elderly people showed that those with severe periventricular white matter lesions were three to five times more likely to have depressive symptoms than those with only mild or no white matter lesions, whilst those with severe subcortical but not periventricular white matter lesions were more likely to have had a history of late-onset depression after the age of 60 years than those with only mild or no white matter lesions[6]. Severe white matter lesions are thought to represent vascular abnormalities, findings that support the notion that vascular pathology contributes to the aetiology of late-life depression.

Functional neuro-imaging techniques have also advanced our knowledge of the pathophysiology and chemical pathology of depression with the introduction of single-photon emission computed tomography (SPECT), positron emission tomography (PET) and magnetic resonance spectroscopy (MRS). Several studies have shown an association between depression, low cerebral blood flow and low metabolic activity. An extensive review of the literature showed evidence for low cerebral activity in the frontal lobes in unipolar and bipolar depressive patients, with an inverse correlation with increased severity of depressive symptoms and an association with low activity in basal ganglia and temporal and limbic regions[7]. Low neurostriatal cerebral blood flow was particularly associated with psychomotor slowing[8] and an association between hypofrontality and negative symptoms in depressive patients[9]. This abnormality is of special interest in the elderly because of the interface between depression and dementia in this age group.

We compared the cerebral perfusion in a group of elderly depressed patients with that in age matched healthy subjects and Alzheimer's disease (AD) patients, using SPECT methodology and hexamethyl propleneamine oxime (HMPAO) as the radioligand[10]. The regional cerebral perfusion values of depressed patients were intermediate between those of the healthy control subjects and the AD patients. This is consistent with the intermediate position of the depressed group on other measures, e.g. radioattenuation on CT scan. In addition to the global impairment in cerebral perfusion, there are topographical abnormalities but the cerebral region thus affected is seen to vary in different studies. Sackeim *et al.*[11] have argued that the traditional statistical paradigms, concentrating on identifying specific brain regions with higher or lower perfusion compared to control subjects, have failed to examine the important issue of identifying the abnormal patterning of regional activity, which would reflect the activity of functional neural networks. Using a novel scaled subprofile model based on factor analytic technique, they demonstrated topographical abnormalities in the temporo-parietal area, largely consisting of polymodal association cortex with strong reciprocal connection with the prefrontal polymodal association cortex. The study by Baxter *et al.*[12] on glucose metabolism using PET strongly suggests that the biological substrate common to depressive states in different patient groups is a reduction in glucose metabolism in the left prefrontal cortex.

The impairment in cerebral perfusion correlates positively with the endogenicity score but not necessarily with the severity of depressive illness[13]. This is in contrast with studies on cerebral glucose metabolism using PET, reporting a positive correlation between the severity of depressive symptoms and glucose metabolic rate. There are some reports on abnormality in the anteroposterior gradient in cerebral perfusion in depressive illness, but these are not consistent.

The temporal sequence of the perfusion abnormality and clinical depression is yet unclear. The impairment in cerebral perfusion improved with clinical recovery, suggesting that the continuing impairment can predict chronicity of the course or frequent relapse of depression. This notion can be examined in further longitudinal studies.

SPECT and PET techniques have also been utilized to investigate the chemical pathology of dopamine and serotonin systems in depression. SPECT studies of D2 receptors showed increased D2 receptor density in the striatum, reflecting reduced dopamine function[14], and an association between increased D2 receptor binding in the left striatum in the anterior cingulate gyrus and clinical recovery with selective serotonin reuptake inhibitors[15]. Studies of the dopamine transport receptors in depression showed increased receptor density in the basal ganglia[16]. Studies

of the serotonin system showed a number of interesting associations. A SPECT study of the brain serotonin transport receptor reported reduced density in depression[17], whilst a PET study of the serotonin type 2 receptor function showed a decrease in receptor density following treatment with desipramine, particularly in the frontal region[18]. Studies of the 5-HT_{1A} system showed a reduction in receptor density in the mesiotemporal cortex in bipolar patients, and in unipolar patients with bipolar relatives[19] and an association between widespread reduction of 5-HT_{1A} receptor binding and depression in medicated and non-medicated depressed patients[20]. Finally, studies of MRS depicting biochemical changes have detected an association between depression and reduced glutamine and glutamate, using proton-MRS[21], and increased phosphomonoesters and decreased ATP values in the frontal lobes of patients with major depression using ^{31}P-MRS[22].

In summary, the findings of neuro-imaging studies in depression add credence and support to the biological basis of depression, refine its diagnostic subgroups and inform its treatment with more specific pharmacological treatments.

Is Imaging Justified in the Investigation of Older People?

D. McWilliam

Ribbleton Hospital, Preston, UK

Dementia is still diagnosable only by clinical examination, but a further battery of diagnostic tests may then be required to clarify the aetiology and identify potentially treatable cases. Any assessment of the cost-effectiveness of these further tests, including neuro-imaging, must compare the relative value of routine testing in all patients against selective testing in cases where there is a high index of suspicion or diagnostic doubt.

Routine testing will detect the small number of patients (about 1%) with a reversible cause for their dementia, but is burdensome, especially in the elderly, and may raise false expectations and lead to false-positive results. It would also identify early cases suitable for drug therapy. Selective testing will result in some treatable cases being missed, but causes less general risk and discomfort and may be more cost-effective, especially in those countries where neuro-imaging remains expensive and difficult, or even impossible, to access[1,2].

Providing cost-effective and accurate diagnosis of dementia therefore presents the clinician with a dilemma. Can neuro-imaging be included in a battery of ancillary investigations devised for routine use in all cases of dementia, or need such tests be carried out only as clinically indicated? The fact that definitive data on the sensitivity, specificity and cost-effectiveness of various

Is Imaging Justified in the Investigation of Older People?

D. McWilliam
Ribbleton Hospital, Preston, UK

Dementia is still diagnosable only by clinical examination, but a further battery of diagnostic tests may then be required to clarify the aetiology and identify potentially treatable cases. Any assessment of the cost-effectiveness of these further tests, including neuro-imaging, must compare the relative value of routine testing in all patients against selective testing in cases where there is a high index of suspicion or diagnostic doubt.

Routine testing will detect the small number of patients (about 1%) with a reversible cause for their dementia, but is burdensome, especially in the elderly, and may raise false expectations and lead to false-positive results. It would also identify early cases suitable for drug therapy. Selective testing will result in some treatable cases being missed, but causes less general risk and discomfort and may be more cost-effective, especially in those countries where neuro-imaging remains expensive and difficult, or even impossible, to access[1,2].

Providing cost-effective and accurate diagnosis of dementia therefore presents the clinician with a dilemma. Can neuro-imaging be included in a battery of ancillary investigations devised for routine use in all cases of dementia, or need such tests be carried out only as clinically indicated? The fact that definitive data on the sensitivity, specificity and cost-effectiveness of various

neuro-imaging techniques are still needed[3] only adds to the problem.

The advent of treatments for dementia and the consequent need to identify early and potentially treatable cases has shifted the assessment of cost-effectiveness from investigation to treatment. The cost-benefit assessment of early treatment of dementia to a health economy has yet to be fully assessed but is likely to far exceed that of any neuro-imaging screening programme. A recent review[4] neatly encapsulates what is now as much a socioeconomic as a medical dilemma in a single statement: ''How much is society willing to spend?''.

Given that these socioeconomic drivers are unlikely to change, clinicians are now seeking to devise assessment protocols for dementia that best address the conflict. Unfortunately, we are still some distance from achieving a consensus view. Some authors[4] advocate routine neuro-imaging as part of a screening procedure in all patients in order to ''include in'' all treatable cases, perhaps avoiding litigation. Others, when attempting to define practice parameters, have regarded neuro-imaging as optional in the differential diagnosis of dementia[5]. Subsequent analysis showed that imaging studies did improve diagnostic accuracy but only with a significant increase in cost[6].

Considerations of cost and, in less well-developed countries, of access continue to determine whether neuro-imaging in dementia is used as a universal screen or only when clinically indicated. Various protocols indicating that neuro-imaging is not required in all patients, but should be a first-line test, especially in younger patients and those cases where there is diagnostic doubt on clinical grounds, have been suggested[7–10]. It is likely that, as costs of treatment increase relative to those of investigation, the use of neuro-imaging as a screening tool rather than a diagnostic aid in dementia will increase.

Clinical Features of Depression and Dysthymia

David G. Folks[1] and Charles V. Ford[2]

[1]*University of Nebraska College of Medicine, Omaha, NE and*
[2]*University of Alabama School of Medicine, Birmingham, AL, USA*

Depression *per se* is not characteristic of later life and should not be interpreted as "normal". Most normal adults make a satisfactory adjustment to the fact of growing older; after all, it is preferable to the alternative. Depression in old age may represent a continuation of a process that began in early life. For example, dysthymia as a chronic condition may extend into later life, or a continuation of cyclical changes of mood may be experienced, with periodic exacerbations of unipolar or bipolar depression. Additionally, some types of depression may originate in later life and the symptomatic presentation may or may not vary from the classical symptomatology. Depression and dysthymia may arise as a component of other psychiatric disturbances. Misdiagnosis or lack of referral for treatment of depression and dysthymia in older adults is due both to the context in which depression appears and the manner of presentation of symptoms[1]. Depression is a spectrum of disorders, rather than a unitary construct, and multiple biopsychosocial factors will influence how clinical features are manifested, as well as response to treatment. A depressive disorder may be diagnosed in accordance with current clinical criteria only if the depressive symptoms actually interfere with work, family or social functioning, or if the individual seeks professional treatment or has received medication for the disturbance[2].

The existing nomenclature may not accurately reflect depressive syndromes in late life. A number of well-established clinical syndromes are documented in the literature, for example depressive pseudodementia, somatization with underlying depression, and other forms of masked depression in individuals who deny depressive symptomatology. Subsyndromal depression may also occur in old age and can progress to a full syndrome of depression. Because of these potential differences in the presentation of depression in late life, epidemiologic data suggest that the elderly have a lower prevalence of major depression than do younger populations[1–4]. The literature has also consistently reported that a low proportion of clinically depressed elderly individuals seek or are referred for psychiatric care[6]. However, despite the inherent problems of describing depression and dysthymia in late life, and the presumed low rates of recognition or referral, depression is probably the most common psychiatric disorder in late life[7–10].

The clinical features of various forms of depression will be described using an outline form. The three clinical entities relevant to the current nomenclature and older adults are: *major depression,* unipolar or bipolar, single episode or recurrent, with or without melancholia, with or without psychotic features; *dysthymic disorders* or depressive neurosis; and *other atypical forms of depression*, i.e. somatization, cognitive impairment, including the reversible syndrome of dementia (pseudodementia) mood syndromes secondary to a general medical condition, and subsyndromal depression. The fact remains that in clinical practice considerable overlap exists for these syndromes, boundaries are often not distinct, and a spectrum of symptomatology is observed.

CLINICAL FEATURES OF THE DEPRESSIVE SPECTRUM

Symptoms of Grief and Pathological Bereavement

The hypothesis that demoralization and despair result from losses or incapacities due to aging seems to have no basis in empirical data. In fact, most surveys of older adults show older individuals to be more contented with their life situations than are those in earlier stages of the life cycle[9–11]. Perhaps when life events are anticipated and rehearsed, grief work can be completed before the loss with effective coping strategies. Grief, a psychologic response to the loss of a loved one, of possessions or of health itself, is associated with feelings of sadness, transient symptoms of gastrointestinal complaints, weight loss and difficulty in sleeping. Symptoms are often intense for several weeks and then typically begin to improve[12]. Many losses can lead to fear, demoralization or loneliness. In vulnerable individuals they may result in the onset, worsening or persistence of a mood disturbance. Pathological grief may include overactivity without a sense of loss, acquisition of symptoms belonging to the last illness of the deceased, frank psychosomatic illness, an alteration of relationships with family and friends with hostility towards specific individuals, and a persistent loss of patterns of social interactions[13–15].

Because older persons themselves, their families or even healthcare professionals can understand the difficulties experienced, depression occurring in the wake of such significant loss may be considered as "normal". This uninformed perspective works against making the diagnosis of clinical depression and interferes with the effective treatment of this painful and potentially life-threatening condition. Spousal bereavement is a common occurrence of late life, associated with prolonged personal suffering, declining mental and physical health and

increased risk of mortality[16]. Among elderly widows and widowers, 20% meet the criteria for major depressive syndrome 2 months after their loss, and one-third of these individuals develop persistent depression for a year or longer[17]. Generally, individuals who are at greatest risk for persistent depression have worse health, more functional and social difficulties and more protracted grief than do bereaved individuals who are not depressed. Whenever major depression occurs, even if precipitated by a significant loss, it should be considered an illness and treated accordingly. As a rule of thumb, if a depressive syndrome occurs within the first 2 months after bereavement and lasts less than 2 months, it should be considered part of the normal grief process and not aggressively treated. However, even within the first 2 months, the depression should be considered a clinically important, treatable syndrome if it is severe or, associated with psychomotor retardation, is accompanied by feelings of worthlessness or suicidal ideation, or occurs in a person with a history of previous major depressive episode[5]. Persistence of severe symptoms beyond several months suggests a condition more severe than the normal grief process.

Symptoms Reflecting Adjustment

Disorders with Depressive Symptoms

The role of social or situational stressors contributing to depression in late life is not well established[18]. Situational stressors may include limited mobility, sensory deprivation, retirement, economic constraint, changing or unsatisfactory living conditions, social isolation, marital difficulty, loss of significant loved ones and/or rejection by children[19].

Of much greater frequency, however, is the development of depressive symptomatology secondary to general medical conditions. When the depressive symptoms accompanying physical illness dramatically exceed the level of symptoms expected, then the diagnosis of adjustment disorder is appropriate. General medical illness resulting in functional disabilities is believed to represent the more significant stressor, contributing to the loss of resources necessary for the maintenance of self-esteem[11,20]. Essentially, depression interferes with basic abilities to think, eat, sleep, love, interact with others, maintain a sense of purpose, experience gratification and maintain self-responsibility[21]. Consistent with the medical outcomes studies[22], depressive symptoms are associated with much social and physical dysfunction, days spent in bed and even physical pain as adverse as any general medical condition. Co-morbid medical illness increases the chronicity and refractoriness to treatment and it may slow recovery rates for patients with various conditions, including heart disease, stroke, hip fracture and dementia[5].

The resolution of stressful events probably depends on a variety of factors, including genetic predisposition, prevailing early life experiences, adequacy of previous adaptive and coping mechanisms, patterns and profiles of premorbid personality and the presence or absence of the support system. Not only may family or social dysfunction influence whether depressive symptoms are experienced by an older adult, but family and social support is apparently critical to the successful outcome in treating the depressed elderly. Blazer has outlined six critical areas as follows: (a) the presence of members of the family or social network who will be available; (b) the interaction of the older adult with family members and other individuals within their community; (c) the integrity of the overall family system and social system; (d) the family and social values regarding the psychiatric disorder; (e) the degree of family and social support with respect to tolerance of symptoms; and (f) other coincidental stressors or life events encountered by the family and social system[23].

Symptoms of Dysthymia

Dysthymic disorder is believed to be less frequent in older adulthood[3]. Co-morbid general medical conditions, cognitive disorders and frequent adverse life events, e.g. bereavement, make the diagnosis of dysthymic disorder quite difficult. Some associated features may include the presence of major chronic stressors, increased physical impairment and more symptoms of anxiety[24]. Generally, dysthymia is less associated with co-morbid Axis I or co-morbid Axis II disorders, and patients with dysthymia tend to be seen in primary care settings rather than by psychiatric specialists[25]. The usual psychologic mechanisms of dysthymia, i.e. self-reproach, guilt and the turning inward of hostile feelings towards loss, are not prominent in later life. However, psychodynamic explanations, i.e. loss of self-esteem and the inability to defend oneself against threats to security, are important in the pathogenesis of late-life dysthymia[26]. The role of narcissistic pathology in the etiology of late-life depression may also contribute significantly to episodes of recurrent depression or defensive grandiosity in response to minor disappointments, or due to self-consciousness or overdependence on approval from others for maintenance of self-esteem, and as a consequence of transitory periods of fragmentation and discohesiveness of the self[27]. Cultural or developmental factors may also contribute to dysthymia. For example, the development of habit patterns emphasizing activity, productivity and achievements can lead to depression and despair at retirement or with the cessation of parenting[28]. Also, as opportunities to interact with cohorts decline, an older individual may not reconcile generative disappointments, and may not proceed from Erikson's[29] developmental stage of generativity to that of integrity (vs. despair)[29].

Symptoms of Major Depression

Major depression is characterized by a persistently depressed mood, loss of interest in usual activities, guilt or other pessimistic thoughts, with accompanying vegetative symptoms reflecting preoccupation with somatic complaints, persistent sleep disturbance, decreased appetite with weight loss, decreased libido, anhedonia and inability to concentrate. Psychotic and delusional symptoms have been reportedly observed with greater frequency in major depressions occurring in later life[4]. Delusional themes are frequently either somatic or persecutory, and are less often characterized as delusions of guilt, sin, poverty, nihilism or jealousy[30]. Feelings of guilt, obsessive rumination, agitation and ideas of reference are frequently found in older adults with major depression. Perceptual disturbances, e.g. hallucinations, may be present but are less frequent than other psychotic symptoms. The prevalence of major depression in the oldest-old is lower than for persons in mid-life, but may be somewhat higher for those who are "young-old", usually estimated at 2–5%[31,32]. Patients with major depression are thought to be more likely to exhibit suicidal ideation. Suicidal ideation is strongly associated with completed suicide. One study has suggested that correlates of suicidal ideation include psychomotor retardation, a history of dysthymia, a previous psychiatric inpatient stay, being a "younger-elder" and having symptoms that reflect feeling "guilty, sinful or worthless"[33]. These correlates of suicidal ideation may be present among individuals who have dysthymia and other minor forms of depression as well.

Symptoms of Bipolar Affective Disorder

Bipolar disorder may be more common in the elderly population than currently recognized. Symptoms of the depressed bipolar

elderly patient may include profound psychomotor retardation, even to the point of frank stupor. This psychomotor retardation mimics both dementia and the inanition associated with physical disease. Mood can be elevated or irritable but may be rather labile, showing a picture of depressive admixture[34,35]. These depressed patients may be unable to provide a meaningful history and/or cooperate with diagnostic procedures. Similarly, the elderly, manic patient may make inappropriate sexual comments and/or advances, or be agitated and/or assaultive, and as a result be regarded as cognitively impaired. Although bipolar patients have usually had a history of mood disturbances in the past, these episodes may have been ‘‘forgotten’’ or repressed by both the patients and primary relatives[36].

LATE-ONSET DEPRESSIVE ILLNESS

Depression in late life may be characterized as of early or late onset. Early-onset depression which recurs in later life may have symptoms similar to previous episodes. Differences in the clinical presentation may be observed in both early-onset and late-onset depressives[37]. Genetic predisposition, significant losses or multiple life stressors may interact with age-related biological vulnerabilities. Biological changes due to the physiologic effects of aging have been verified by the study by Schneider[38], showing that unmedicated, elderly depressed subjects demonstrated higher monoamine oxidase (MAO) activity than sex- and age-comparable controls.

Recent studies have proposed that neurobiologic and/or psychosocial factors may predispose an older individual to depression or dysthymia[39]. MRI-defined vascular depression has been identified as a late-onset, non-psychotic type of depression, seen more often in individuals with no family history of depression, together with symptoms of anhedonia and increased psychosocial impairment[40]. Other studies have verified the increasing incidence of depression among individuals with cerebrovascular risk factors, MRI findings associated with vascular disease and symptoms of apathy, together with diminished life quality[41]. Central nervous system degeneration, for example, from the biochemical changes in Alzheimer's disease or other complaints may predispose to an increased incidence of depression[42].

Age of onset has been used as a correlate for late-life depressive symptomatology. Depressive symptoms may be found to be more frequent among the old-old compared to the young-old, with approximately 20% compared to less than 10% in the community[43]. This higher frequency of depression among the old-old may be explained by a higher proportion of women, more general medical problems, more cognitive impairment and lower socioeconomic status. When these factors are controlled, no relationship exists between depressive symptoms and advancing age[44]. Nonetheless, depression is associated with disability among the old-old and a number of studies have illustrated the association between depression and frailty, functional disability and co-morbid general medical problems and/or cognitive impairment[45–47]. Essentially, having more than two previous episodes as compared to two or less is related to younger age, earlier age of onset, dysthymia, feelings of worthlessness, difficulty concentrating, slowed thoughts, suicidal ideation, symptoms of anxiety and decreased perception of social support. Patients with multiple recurrent episodes are also thought to be at higher risk for more severe illness[48]. Late-onset depression is more frequently associated with structural brain changes and cerebrovascular disease, while early-onset depression seems to be more influenced by family and genetic factors. Compared with early-onset depressives, patients with late-onset depression tend to show more loss of interest, less pathological guilt, more psychosis and more generalized anxiety. These correlates of depressive symptomatology based on age of onset suggest a certain heterogeneity in depression of old age.

Table 74.1 Somatization: principles of clinical management

1. The presentation is considered in the context of psychosocial factors, both current and past.
2. The diagnostic procedures and therapeutic interventions are based on objective findings.
3. A therapeutic alliance is fostered and maintained involving the primary care and/or psychiatric physician.
4. The social support system and relevant life quality domains* are carefully reviewed during each patient contact.
5. A regular appointment schedule is maintained for outpatients, irrespective of clinical course.
6. The patient dialogue and examination and the assessment of new symptoms or signs are engaged judiciously, and usually primarily address somatic rather than psychologic concerns.
7. The need for psychiatric referral is recognized early, especially for cases involving chronic symptoms, severe psychosocial consequences or morbid types of illness behavior.
8. Any associated, coexisting or underlying psychiatric disturbance is assiduously evaluated and steadfastly treated.
9. The significance of personality features, addictive potential and self-destructive risk is determined and addressed.
10. The patient's case is redefined in such a way that management, rather than cure, is the goal of treatment.

* Quality of life is an elusive concept but includes the psychosocial domains of occupation, leisure, family, marital, health, sexual and psychological functioning.
From Folks *et al.*[55], with permission.

Atypical Forms of Depression

Depressive illness, particularly of late onset, may present without prominent mood disturbance[19]. Atypical forms of depression, or masked depression, are thus common among older individuals[19]. Masked depression is characterized by the denial of feelings of depression or the lack of complaints of sadness or dysphoria. The dysphoric affect is often prominently masked by somatic complaints, e.g. fatigue, pain, gastrointestinal upset, concentration difficulties or diminished energy[49]. These individuals who manifest prominent somatic symptoms of depression are prone to attribute symptoms of depression to their medical illnesses[10]. Two forms of somatization, hypochondriasis and conversion, may predominate in the clinical picture. The clinical approach to somatization is outlined in Table 74.1.

Hypochondriasis is a common form of masked depression in the elderly and may increase the risk for attempted suicide[50]. This ‘‘secondary’’ form of hypochondriasis must be differentiated from primary hypochondriasis, a persistent somatoform disorder that tends to have its onset in the third or fourth decade of life and persists. Hypochondriasis *per se* is *not* more prevalent in the elderly and its onset in later life should not be considered a part of normal aging, but rather reflective of psychologic distress, particularly depression[51–53]. Conversion symptoms or pain that occurs in an elderly person should also raise the question as to the presence of underlying depression, even when no prominent mood disturbance is found[54,55]. In the nursing home setting, a patient may not meet the clinical criteria for depression on patient interview but be observed to have depressive symptoms in the context of somatic complaints. Apathy, withdrawal and isolation may be clues that depression is present. On the other hand, a patient in a long-term care facility may become abruptly agitated with sleep disturbance and prominent somatic complaints, which should increase an index of suspicion for depression.

Table 74.2 Diagnostic features distinguishing depression from dementia

Depression	Dementia
Depressive symptoms	Euthymia
Subacute onset	Insidious onset
History of depression more	History of depression less
Aphasia, apraxia, agnosia absent	Aphasia, apraxia, agnosia present
Orientation intact	Orientation impaired
Concentration impaired	Recent memory impaired
Patient emphasis on memory complaint	Patient minimizes memory complaint
Patient gives up on testing	Patient makes effort on testing

Adapted from Wells[56].

Depression in late life may be masked not only by somatic complaints but also by cognitive difficulties, reflecting yet another atypical form of depression observed in older adults. Difficulty in concentrating or memory loss may result in the clinical picture of "depressive pseudodementia"[56]. This *dementia syndrome of depression* represents a reversible syndrome of dementia that may be clinically indistinguishable from irreversible dementias (Table 74.2)[57,58]. These individuals frequently make little effort to cooperate with mental status examination and the patient answers "Don't know" to many questions. However, notable losses of both recent and remote memory are observed, and these patients may show marked variability on the performance of tasks of similar difficulty. In some cases, depression may be diagnosed retrospectively after a favorable response to a trial of antidepressant medication[19]. Further complicating the issue, in about 20% of cases of true dementia a major depression may coexist[59]. In these cases, both mood and function may improve when treated with an antidepressant therapy, but the basic cognitive impairment remains.

Depression Secondary to a General Medical Condition

Depression may be intimately related to general medical disease or other "organic" influences. Of course, the relationship between somatic symptoms in the medically ill elderly and complaints of depression may be complex; older individuals are presumably more vulnerable to the stresses of poor health and disability that interfere with body image, self-esteem and autonomy. Co-morbidity is the rule, rather than the exception, and linked significantly to functional decline across multiple parameters with increasing age. Co-morbidity of depression with medical illness is associated with poor physical, mental and social functioning, all of which compound the patient's ability to enjoy the quality of life. Not only may medical problems act as precipitators of depression, but many direct effects of medical conditions induce a secondary form of depression (Table 74.3)[9,10]. Medications, including anxiolytics, antihypertensives and neuroleptics, may induce a syndrome of depression. Polypharmacy and drug interaction may further serve to culminate in a depressive illness. The association between depression and general medical–surgical problems may be summarized as follows: (a) physical disease is associated with narcissistic injury, loss of autonomy, pain and fear of impending death, frailty (to be discussed) and diminished quality of life; (b) physical illness may directly (e.g. a cerebrovascular accident) or indirectly (e.g. hypercalcemia) cause a depressive syndrome; or (c) medications used to treat medical diseases may themselves induce depression. These parameters are more significantly affected than in an individual with depression alone or general medical illness without depression[60]. Thus, among individuals with depression in the context of dementia, individuals who experience co-morbid depression and general medical illness are less active, with fewer social contacts that explain increased disability risk[45]. Physical immobility and social isolation in turn increases disability over time, which further decreases mobility and social interactions, placing the person at risk for physical, psychological and social impairment[61,62]. For some individuals, the end result is a downward spiral in health, functioning and quality of life, a syndrome described by geriatricians as "frailty and failure to thrive". This manifestation is characterized by weight loss, weakness, fatigue, inactivity, decreased food intake and depression. Physical signs that may accompany these symptoms include sarcopenia, balance and gait abnormalities, deconditioning and decreased bone mass[63,64]. Failure to thrive specifies an end-stage of frailty that is characterized by unchecked weight loss, severe muscle wasting, apathetic depression and a host of physiologic abnormalities, including hypoalbuminemia, low creatinine, anemia, bicuspid ulcers and untimely death[65]. Indeed, depression in the elderly is closely related to the state of one's physical health.

Table 74.3 Medications reportedly associated with depression

Cardiovascular drugs	Hormones	Psychotropics
α-Methyldopa	Conjugal estrogens	Analgesics
Reserpine	ACTH (corticotropin) and glucocorticoids	Anti-parkinsonian
Propranolol	Anabolic steroids	Antihistamines
Guanethidine		Benzodiazepines
Clonidine		Other sedative hypnotics
Thiazide diuretics		
Digitalis		Typical neuroleptics
	Anti-inflammatory/	
Anticancer agents	anti-infective agents	Others
Cycloserine	Non-steroidal anti-inflammatory agents	Cocaine (withdrawal)
		Amphetamines (withdrawal)
	Ethambutol	L-dopa
	Disulfiram	
	Sulfonamides	Cimetidine
	Baclofen	Ranitidine
	Metoclopramide	

Adapted from Agency for Health Care Policy and Research[78].

Subsyndromal Depression

Subsyndromal depression is defined as depressive symptoms that do not qualify for a formal mood disorder using current clinical criteria. However, several studies have revealed that subthreshold depressive states can be associated with adverse clinical outcome. Additionally, subsyndromal depression may be a risk factor for subsequent major depression[66]. Subthreshold depressive disorder tends to be a heterogenous group of milder forms of depression with symptom patterns qualitatively distinct from more severe depressions such as major depression. According to the Berlin aging study, a subthreshold depression can be characterized in two ways among the elderly[67]; first, as a quantitatively minor variant of depression or a depression-like state, with fewer symptoms or with less continuity; second, as a condition qualitatively different from major depression, with fewer suicidal thoughts or feelings of guilt or worthlessness, while worries about health and weariness of living occur with a similar frequency.

CLINICAL FEATURES AND PROGNOSTIC FACTORS

The paucity of controlled studies in the diagnosis and phenomenology of depression and dysthymia in older adults restricts

meaningful prognostication. Depression may be reflected in behavioral changes in the elderly, for example increased clinging, dependent behavior, phobias or avoidance of previously enjoyable activities, perhaps representing a variant of anhedonia. No conclusive evidence has shown that major depression is more chronic in later life; in fact, most psychogeriatricians are convinced that the outcome of adequately treated depression, uncomplicated by medical disease, is as good as the outcome from younger individuals. A caveat is that the risk of recurrence may be greater for older depressives[68,69]. Blazer[26] has noted the tendency for some older individuals to show only partial improvement not fully recovering from an episode of major depression. Thus, in some cases residual symptoms may persist even when response to treatment is definitive—this treatment resistance is more attributed to co-morbidity than to age *per se*.

Accurate and early diagnosis and adequate and aggressive treatment are important considerations in late-life depression and dysthymia. Patients should be screened, with history, questionnaires, observation, collateral information and the use of screening devices, such as the Geriatric Depression Scale[70] or the Center for Epidemiological Studies Depression Scale (CESD)[71], both of which are validated in older depressives and useful in the overall assessment process. These self-assessment instruments, together with the Hamilton Depression Rating Scale[72], an interviewer assessment agent, are useful for assignment of psychiatric diagnosis of depression. Other questions, designed to establish cognitive, nutritional and functional status, social function and general health perceptions, together with review of medications, medical work-up and laboratory assessment as indicated, are necessary in early intervention. Keller *et al.*[73] reported that depressed patients who did not receive treatment until long after the onset of depressive symptoms had the worst prognosis. These investigators suggested that early intervention is indeed the most effective means of reducing chronicity. Therapy must proceed across multiple domains simultaneously. This includes the mobilization of the social support system, the use of antidepressant medications, psychotherapy and efforts to improve physical or social functioning[74,75]. Among psychotherapeutic options, cognitive–behavioral therapy has been utilized most, with a few reports involving interpersonal psychotherapy. Other behavioral interventions range from prescribing regular group activities, physical exercise such as walking, and training exercises for increased independent functioning. Although few in number, studies of comprehensive interventions using all of the approaches outlined above have demonstrated efficacy comparable to that found in younger adults[76,77]. These existing studies are preliminary but promising, in view of the reduction in functional disability and symptomatic relief, together with improved quality of life and, ultimately, reduction in the healthcare cost associated with late-life depression.

CONCLUSION

The categorical approach to depression and dysthymia in late life continues to reflect the current nomenclature. Ultimately, the diagnosis and management of depression and dysthymia is allied with the traditional medical model. This approach enables the clinician to provide specific therapies for distinct diagnostic entities and provides the patient with a number of excellent biological and psychosocial interventions. However, classical symptoms may be overshadowed or replaced by a variety of other symptoms, in which the mood disturbance is not prominent. Thus, the key to the diagnosis and effective intervention of depression in old age is to maintain a high index of suspicion and attend to the functional disability and quality of life issues posed by late-life depression.

Outcome of Depressive Disorders: Findings of a Longitudinal Study in the UK

Vimal Kumar Sharma
University of Liverpool, UK

A high prevalence of depressive disorders among the elderly has been reported by different community studies (*see* reviews[1,2]). More recent epidemiological studies[3–9] using standardized methods have also reported similar prevalence rates of depressive disorders in the range 8–15% in randomly selected community samples. It is not clear whether the high prevalence rate is due to chronicity of the disorder or to a high incidence rate of depression in this age group.

So far there have been few large-scale longitudinal studies of community-based elderly depressed subjects. Most of these studies have reported that 30–60% of the depressed elderly were continually ill[10–15]. Some studies have examined the prognostic factors associated with the poor outcome. Physical illness, handicap, female sex, poor social support, high depression score and anxiety and neuroticism, lack of satisfaction with life and feelings of loneliness are some of the factors reported to be associated with the poor outcome[12,14,16–21]. Kivela[22], in her 5 year follow-up study, reported organic outcome in 12% for major depression and 9% for dysthymic disorder. In contrast, Henderson *et al.*[16] found none of their 24 community cases of depression (ICD 10) to be organic cases after 3–4 years. Many of the studies have also reported that the majority of the depressed elderly never receive appropriate treatment[10,13,23–25].

Community studies[15,16,22,26,27] have reported increased mortality in depression. There have been a few relatively shorter (1–3.5 years) follow-up studies[10,29] which found no significant association between depression and mortality. In another study, when factors such as age, physical health and social conditions were taken into account, depression did not predict increased mortality[18].

Tannock and Katona[30] reviewed the literature and concluded that subsyndromal depression is common among the elderly and that very little is known about its nature and outcome.

Where the symptoms of an illness appear to lie on a continuum of severity with normal behaviour, as in depressive illness, variations in disease level might be found between studies because they use different cut-off points and/or record different types of symptoms, rather than because there are true differences in illness levels. Such spurious differences may also arise between different waves of interviewing in the same longitudinal study if the interpretation of symptoms is not standardized, and may also occur if the interviewers of subsequent waves are not blind to the findings of previous waves.

A further problem with such studies is that some psychiatrists assume depression to be a unitary disease but nevertheless do not agree on what conditions are to be excluded; e.g. some would include bereavement and adjustment disorder if the principal symptom is one of depression. Others would distinguish between major depressive disorders and dysthymia, or between endogenous and reactive, or neurotic and psychotic depression and might or might not recognize brief recurrent depression.

Cole and Bellovance[31], in their review of five community-based studies of depression in old age, highlighted such methodological limitations. They recommended that a large number of depressed elderly (based on explicit diagnostic criteria and reliable measures) should be followed up for a longer duration with specific outcome categories. Outcome assessments should be blind and reported at specific time points (e.g. every 6 months) during the follow-up interval. A continuously depressed elderly cohort should be examined closely to determine the sustaining factors of their depression.

This special article contains findings of the outcome data of the depressed elderly in the Liverpool longitudinal study.

The subsample for this study included 120 index AGECAT cases of depression and 47 of subcases of depression and 82 other subjects. The age distribution of each diagnostic group was similar. More women were present among the cases compared to subcases of depression and non-cases. Most subjects were in social class 3, 4 and 5. Around 40% of both cases and subcases of depression were living alone and this was higher than for non-cases. Stressful events, such as bereavement, illness in the family, house break-ins, family disputes in the preceding month, were more often recorded for subjects of the depressive neurosis group.

The overall dropout rate at 5 years was 28% for cases of depression, 30% for subcases of depression and 26% for other non-cases.

Over 5 years, 41 of 120 cases (34%) died, also 12 of 47 subcases of depression (26%) and 9 of 54 non-cases (17%). The risk of dying within 5 years was 2.1 times higher for the cases of depression compared to non-cases (95% CI, 1.1–3.9). Of the surviving and available cases of depression, 54% (43/79) at year 3, 43% (23/53) at year 4 and 54% (25/46) at year 5 had sufficient psychopathology to reach AGECAT case levels for some kind of mental illness. A further 18% (14/79) at year 3, 17% (9/53) at year 4 and 9% (4/46) at year 5 had psychopathology at the subcase level of depression.

LONGITUDINAL OUTCOME

The outcome of the cases of depression is given in Figure 1. Forty-six of the cases of depression had a complete 5 year evaluation. Eleven (24%) had sufficient symptoms to reach AGECAT case levels at all follow-up assessments. Another 11 (24%) reached AGECAT case levels at two of the three follow-up waves, whilst the other 14 (33%) reached case levels at only one. The remaining 10 (22%) never reached AGECAT case levels at any of the 3, 4 and 5 year follow-up waves. The AGECAT diagnosis at any follow-up wave was depression in 70% of the interviews. Those (30%) who were diagnosed as another type of case, other than depression, had a high depression score. Only one of the year 3 cases of depression was on antidepressant treatment and none of year 4 and 5 cases of depression were on antidepressants at the time of their interviews.

Outcome of the Subcases of Depression

As many as 16 (34%) of the 47 subcases of depression were AGECAT cases at year 3, most of them cases of depression. Their 5 year outcome is given in Figure 2.

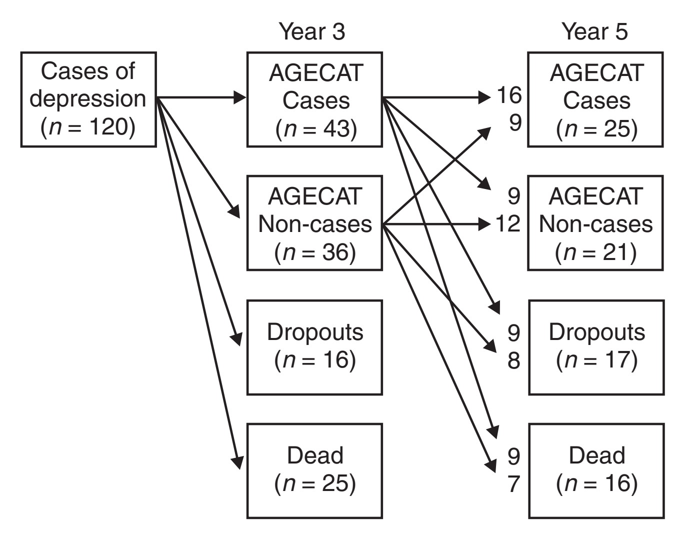

Figure 1 Outcome of the cases of depression (from ref. 34, with permission)

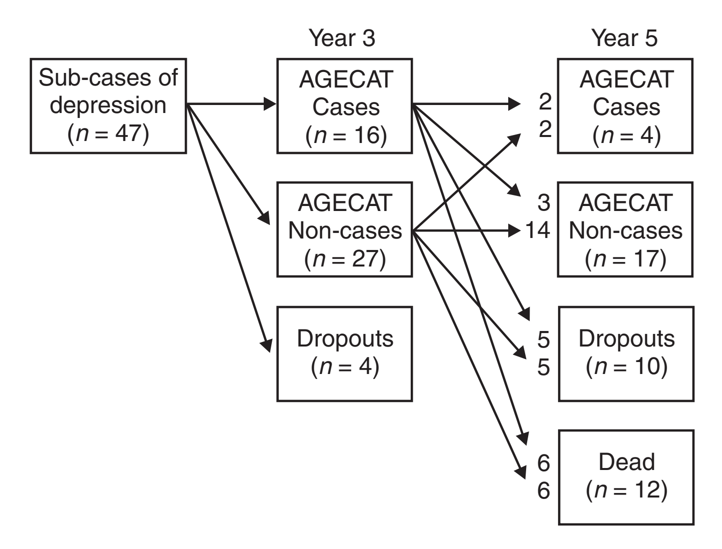

Figure 2 Outcome of the subcases of depression (from ref. 34, with permission).

Organicity and Outcome of the Cases of Depression

In all, 30 (25%) of the 120 cases of depression had co-morbid organic symptoms (AGECAT levels 1–2) at the index assessment. By year 5, nine (30%) had died and seven (23%) had dropped out. Of the remaining 14, 12 (40%) were AGECAT cases and two were non-cases. Seven (6%) of the 120 cases of depression (15% of the surviving cases) had become organic cases at the 5 year follow-up. Five of them had already had some organic symptoms (AGECAT levels 1 or 2) at the start of the study.

Predictors of Outcome

Univariate analyses were done to see which index variables (age, gender, marital status, social class, stressful events, living conditions, social support, physical illness, depression type (DP and DN), depression score and psychiatric co-morbidity) were predictive of a poor outcome for the depression cases that had survived. Anxiety caseness and a depression score of 30 were particularly predictive of a poor outcome in this sample. Those aged under 75 years did better than those 75 years and older.

A prospective follow-up of the cases of depressive disorders at shorter intervals is the strength of this study. Its findings highlight the importance of the mental health needs of this population. Further studies are needed to discover whether drug treatments or other psychosocial interventions can alleviate depression in elderly people living in the community.

Longitudinal Studies of Mood Disorders in the USA

Dan G. Blazer

Duke University Medical Center, Durham, NC, USA

Depressive disorders in late life tend to recur or persist and change the course of a person's life through time. For this reason, the assessment of depression through time necessitates an accurate understanding of the longitudinal course of depressive disorders. For this reason, when the Psychobiology of Depression Study Group began their extensive study of inpatient and outpatient persons in adulthood (but not including old age), they incorporated an extensive longitudinal study into their methodology. Results from this study revealed that 1 year following identification of an index episode of major depression, 50% of the cohort 59 years of age and younger had recovered, but the annual rate of recovery decreased to 28% by the second year and to 22% by the third year. These investigators determined that recovery from an index episode of major depression was most likely to occur within the year following identification of the episode. Among those individuals who do recover, 24% suffered a relapse within 3 months of the recovery; 16% of the individuals who identified suffering from an index episode remained ill throughout the first year. The cohort has now been followed for 15 years (original age of 18–59 with the current cohort now between 33–74); 85% of those who recovered from the index episode relapsed at least once over the 15 years and 58% of persons who recovered and remained well for 5 years relapsed over the next 10 years. Female gender, a longer index episode of depression, more prior episodes and never marrying all contributed to an increased likelihood of relapse.

There has been no equivalent study of the outcome of late-life depression within the USA that has currently been reported in the literature. However, an ongoing study by Duke University investigators has found that rates of chronicity, recovery and relapse are virtually identical to those reported by Keller and colleagues for younger age groups. The remainder of studies in North America have concentrated primarily upon outcome in controlled treatment trials. The Pittsburgh group found that over 3 years, subjects treated with optimal doses of antidepressant medications relapsed at a rate of between 30% and 40% over 3 years.

Longitudinal Studies of Mood Disorders in the USA

Dan G. Blazer
Duke University Medical Center, Durham, NC, USA

Depressive disorders in late life tend to recur or persist and change the course of a person's life through time. For this reason, the assessment of depression through time necessitates an accurate understanding of the longitudinal course of depressive disorders. For this reason, when the Psychobiology of Depression Study Group began their extensive study of inpatient and outpatient persons in adulthood (but not including old age), they incorporated an extensive longitudinal study into their methodology. Results from this study revealed that 1 year following identification of an index episode of major depression, 50% of the cohort 59 years of age and younger had recovered, but the annual rate of recovery decreased to 28% by the second year and to 22% by the third year. These investigators determined that recovery from an index episode of major depression was most likely to occur within the year following identification of the episode. Among those individuals who do recover, 24% suffered a relapse within 3 months of the recovery; 16% of the individuals who identified suffering from an index episode remained ill throughout the first year. The cohort has now been followed for 15 years (original age of 18–59 with the current cohort now between 33–74); 85% of those who recovered from the index episode relapsed at least once over the 15 years and 58% of persons who recovered and remained well for 5 years relapsed over the next 10 years. Female gender, a longer index episode of depression, more prior episodes and never marrying all contributed to an increased likelihood of relapse.

There has been no equivalent study of the outcome of late-life depression within the USA that has currently been reported in the literature. However, an ongoing study by Duke University investigators has found that rates of chronicity, recovery and relapse are virtually identical to those reported by Keller and colleagues for younger age groups. The remainder of studies in North America have concentrated primarily upon outcome in controlled treatment trials. The Pittsburgh group found that over 3 years, subjects treated with optimal doses of antidepressant medications relapsed at a rate of between 30% and 40% over 3 years.

Outcome of Depression in Finland

Sirkka-Liisa Kivelä
University of Turku, Finland

In the early 1980s, an epidemiological study of depression was carried out among the population aged 60 years or over ($n = 1529$) living in the municipality of Ähtäri in south-western Finland. DSM-III criteria were used to diagnose depression in interviews and examinations and 264 depressed persons (91 men and 173 women) were discovered; 42 met the criteria for major depression, 199 for dysthymic disorder, 21 for atypical depression and two for cyclothymic disorder.

The depressed persons were intensively treated in a primary care setting for about 2 years after the epidemiological study. The treatment consisted of individual psychological support by a general practitioner, antidepressive medication, counselling about nutrition and physical exercise and social support from the families, relatives, neighbours and home care personnel. Later, a less intensive treatment schedule, consisting of psychological support by a general practitioner and antidepressive medication, was arranged for those who had not recovered.

1 YEAR AND 5 YEAR CLINICAL OUTCOMES

Nearly half of both major depressive and dysthymic patients were non-depressed after 1 year (Table 1). The proportion of depressed subjects tended to be higher among the dysthymic patients, while the proportions of demented subjects and deaths tended to be higher among the major depressive patients. After 5 years, the proportion of recoveries was higher among the dysthymic patients, and the death rate was higher among the major depressive patients. Every fourth subject was depressed in both groups.

Table 1 One year and 5 year outcomes of major depressive and dysthymic older patients treated in primary health care

	1 Year outcome		5 Year outcome	
	n	(%)	*n*	(%)
Major depressive patients				
Non-depressed	19	(45)	5	(12)
Depressed	11	(26)	11	(26)
Demented	6	(14)	5	(12)
Dead	6	(14)	19	(45)
Refused to participate			2	(5)
Total	42	(100)	42	(100)
Dysthymic patients				
Non-depressed	79	(40)	71	(36)
Depressed	91	(45)	52	(26)
Demented	6	(3)	18	(9)
Dead	20	(10)	50	(25)
Refused to participate	3	(2)	8	(4)
Total	199	(100)	199	(100)

FACTORS RELATED TO RELAPSES OR LONG-TERM COURSE

Major depression had a definite tendency for a relapsing course during the 5 year follow-up, even without any special stressors in life or physical illnesses after recovery. The depressed patients who developed a physical disease and whose physical health deteriorated during the treatment had a high risk for non-recovery and a long-term course of depression. Many of these patients had suffered from poor self-appreciation and diurnal variation of symptoms at the onset of the treatment.

The results support the following proposals for clinical practice. Major depressive patients should be followed up after recovery in order to detect their possible relapse and to increase the probability of recovery. Intensive antidepressant and psychotherapeutic treatment and adequate treatment of physical diseases should be arranged for depressed patients who develop a physical disease or whose somatic condition deteriorates due to a previous physical disease. Cooperation between psychiatrists and general practitioners is needed in the above two cases.

MORTALITY

Major depressive patients had a high death rate, which was not explained by their poor physical health. These results suggest that there may be biological factors associated with major depression that increase the risk of death or the risk of the development of physical diseases leading to death. The mortality of dysthymic patients was also higher than that of non-depressed persons, but their high mortality was explained by the high number of physical diseases.

Longstanding depression was a predictor for high mortality, independently of the physical diseases present at the onset of the treatment of depression. The physical diseases that occur during the treatment and predict a longstanding course may explain the high death rate seen here.

These results also underline the need for intensive and adequate treatment of depression and physical diseases in depressed older persons.

Physical Illness and Depression

Mavis E. Evans

Wirral and West Cheshire Community NHS Trust, Bebington, UK

EPIDEMIOLOGY

The prevalence of depression in the general population worldwide is usually found to be 3–8%[1–3]. The prevalence of major depression has been shown to be no higher in the elderly than the young, although these findings do not allow for the co-morbidity of physical illnesses or dementias[4]. Subthreshold or minor depressions have many different names and definitions, thus causing widely differing prevalence rates to be quoted. Categorical definitions of depression do not fit well with the range of symptoms and severity seen in normal clinical practice. However, it is generally accepted that the burden of depression among the elderly is high and an accepted measure of diagnosis is necessary to allow communication with patients, relatives and professional colleagues.

"Caseness" can be considered to be the severity of depression at which the majority of professionals would consider some form of intervention appropriate. Prevalence of this degree of depression is reported as 10–15% of the elderly in the community[5–6], 15–30% of those attending primary care facilities[7–8], 15–50% of those in hospital[8–10] and 30–40% of those in institutional care[8,11].

DIAGNOSIS

Depression cannot be diagnosed unless it is first considered a possibility, neither will it be appropriately treated unless it is considered pathological. Depression may be missed when too much emphasis is placed on the presenting complaints of, for example, lethargy, anorexia or pain[12]. Depression and feelings of worthlessness may cause failure to complain of symptoms of physical illness or to ask for help. It may cause non-compliance with medication and other treatments, self-neglect or non-attendance at clinics. Alternatively, the lowering of self-esteem and decreased ability to cope can lead to increased attendance at clinics.

The lack of a concise definition for depression in the elderly makes the establishment of validity a difficult task, which can only be examined by longitudinal follow-up of patients to see what happens to their symptoms[13]. Somatic symptoms, e.g. lack of energy, poor concentration and weight loss, may be due to the physical illness or ageing, not depression; even experienced clinicians may have difficulty attributing such symptoms to physical or psychiatric causes. Even feelings of life not being worth living and wishing to die are not always associated with depressed mood; poor subjective health, disability, pain, sensory impairment and living in an institution have been shown to be associated factors in the absence of depressive illness[14].

The elderly tend not to admit to feelings of depression and relatives may be unaware of the condition[15]. Somatization, "the tendency to experience and communicate somatic distress and somatic symptoms unaccounted for by relevant pathological findings, to attribute them to physical illness and to seek medical help for them"[16] is increasingly recognized. Somatization can still occur in those with genuine physical illness. The somatic symptoms of depression are similar to those of a chronic illness, such as cancer, and it must be remembered that depression and physical illness often coexist[17].

Hypochondriasis is a recognized symptom of depression in the elderly population[18]. However, in this age group, rigorous steps must be undertaken to exclude physical problems before ascribing symptoms to hypochondriasis or somatization[17,19]. That such patients are depressed is inferred from their good response to standard treatments for depression[20].

The 1991 NIH Consensus Statement on diagnosis and treatment of depression in late life concluded: "What makes depression in the elderly so insidious is that neither the victim nor the health provider may recognize its symptoms in the context of the multiple physical problems of many elderly people". DSM-4 allows somatic symptoms to be counted towards the diagnosis of depression if there is any possibility of psychological aetiology, a more inclusive and accurate means of diagnosis than previously.

MORBIDITY AND MORTALITY

Psychiatric morbidity in hospitals is higher than in the general population. Surveys of wards and clinics do not completely establish an association between psychiatric and physical morbidity because they may be biased for selective referral patterns: psychological symptoms can lead to help-seeking behaviour for physical illness in an individual who had previously been able to tolerate his/her physical problems. Similarly, they may influence a GP on whether or not to refer to hospital. Stress may be as important in triggering help-seeking behaviour as in triggering actual illness. In addition to the degree of distress, many other factors determine whether or not an individual will seek help, including religious and social values, socioeconomic background and personality.

Affective disorder in the elderly is strongly associated with physical ill-health[19]: "whether or not such an illness has a direct aetiological relationship to the affective disorder, its practical importance must be considered, for it is bound to influence the course and outcome of the psychiatric condition". Other studies have found that depression leads to increased mortality[21–23] over and above age effects, the prognosis worsening with severity of

depression. Depression in the elderly may be due partly to a biological ageing process, which would directly increase mortality and morbidity[20,24]. Burvill and Hall[25] showed increased mortality in depressed elderly patients ($n = 103$, age 60+) followed for 5 years if they were aged 75+, had impaired mobility or showed poor recovery with residual symptoms or chronicity. There were two peaks of increased mortality, one early in the disease and one late. Cardiovascular or pulmonary disease and malignancies were the predominant causes of death. The results are similar to those of Murphy *et al.*'s 4 year follow-up[26], who also postulate that increased mortality seen in the depressed elderly (especially the men) was not due to differences in physical health alone. They suggest:

1. Inadequate treatment of the depression, leading to cardiovascular complications from the antidepressant but no benefit to the patient; the depression itself can also provoke cardiac death, especially in men.
2. "Subintentional suicide" in those who "turn their faces to the wall".
3. Residual depressive invalidism, causing poor nutrition and decreased mobility; with attendant complications of susceptibility to infection, fractures, bedsores, etc., all contribute to the increased mortality.

Mortality in hospital was found to be significantly higher in those depressed but over 30% of those discharged had died within, on average, 5 months, whether depressed or not[27]. The authors also noted that survivors with depression consumed more healthcare resources than did the non-depressed survivors. Among the depressed elderly, 40% have chronic poor physical health[28]; they use and need more medical services[29,30] than the non-depressed, but also use fewer social and recreational services[29]. An association has been found between poor mental health and subsequent physical disease, suggesting that positive mental health may significantly retard the decline in physical health with increasing age[31].

Physical illness affects the capacity for independent living, resulting in altered relationships with others, lowered self-esteem and vulnerability to depression. Serious illness may be seen by some as an unpleasant reminder of mortality, bringing apprehension and fear. Continuing physical illness is a poor prognostic factor for depression, although whether this is due to a biological relationship or to the psychological strain of being ill is uncertain.

Mortality in acute medical inpatients is significantly higher in those with associated depression, although the direction of causality is not established, e.g. Silverstone[32] followed consecutive admissions for myocardial infarction, subarachnoid haemorrhage, pulmonary embolus or upper gastrointestinal haemorrhage for 28 days post-admission; 34% were depressed and 47% of these had life-threatening complications or died, compared with 10% of those not depressed.

PHYSICAL ILLNESS AND DEPRESSION

Mood disturbance can result from structural brain disease, alterations in neurotransmitter concentration or activity caused by drugs or biochemical disturbance. These affective symptoms may present during a physical illness or be the initial symptom of an otherwise occult physical disorder. Depression may be:

1. The result of an illness, especially a painful or disabling one.
2. Iatrogenic, e.g. the result of steroid treatment.
3. A symptom of the physical illness, e.g. hypothyroidism.
4. An aetiological factor, e.g. alcohol abuse secondary to depression.
5. A depressed patient adopting the sick role as a coping mechanism.
6. A common aetiological factor, such as bereavement, may cause both depression and physical illness.
7. Coincidental.

The elderly are particularly susceptible to the side effects of drug treatment[33], especially as they are often subject to polypharmacy[34,35]. Patients with drug-induced depression often have a past or family history of depression and the drug may have precipitated the disease by affecting the levels of available neurotransmitters[34]. Depression can often be alleviated by cessation of the drug, although some patients will also require antidepressant treatment. The combination of a susceptible patient and a depressogenic drug may precipitate a depression sufficiently severe to lead to suicide[34].

Subjective rating of general health has been shown to be independently associated with depression in the elderly, including the very old[36–38]. This can lead to presentation at primary care or emergency facilities, unnecessary investigations and risk of iatrogenic disease, and lower quality of life. Recognition and treatment of the depression may lead to improvement in the patient's subjective perception of his/her health.

Physically ill depressed patients are more likely to be admitted to hospital than those who are not depressed[39]. Depressed patients have higher use of all categories of medical care, including admissions, laboratory tests and emergency department visits[30].

The presence of significant psychiatric disorder has been shown to adversely affect the course of medical admission[40,41], affective disorders in particular prolonging length of stay[42–44] (although the study by Ramsay[45] did not confirm this) and increasing the likelihood of admission to residential care[46]. Psychiatric intervention has been shown to increase recovery rate, reduce duration of stay, reduce the need for residential care after discharge and therefore reduce costs[47,48].

ADJUSTMENT DISORDER

Lipowski[49] has proposed that the subjective significance of an illness and its treatment, e.g. amputation, cancer, combined with the patient's personality and social circumstances, is the key to the psychological response. The variety of physical illnesses found with depression would support this view. Depression may be a reaction to physical problems; it occurs more frequently in those with increasing numbers of medical diagnoses and may be precipitated by developing new physical illnesses[21,50]. All illnesses except the very trivial involve an element of psychological adjustment. Serious medical illness is likely to be a potent psychological stressor, affecting body image, self-esteem, the sense of identity and the capacity to work and to maintain social, family and marital relationships[51]. However, the majority of people adapt their lives to the demands of their illness, maximizing their prospects of recovery and return to previous levels of activity.

In the elderly, physical illness is frequently chronic and may worsen with time. This, combined with the losses suffered by many elderly people, such as loss of status and income on retirement, loss of friends and family by death and the fear of loss of independence and dignity due to the illness itself, can lead to the adjustment disorder merging imperceptibly into a depressive illness. This can be considered secondary depression[52], the depression following or paralleling a life-threatening or incapacitating medical illness. However, the prevalence of this type of depression is unknown, as it is difficult to differentiate from depression related to other stressors and previous history. Patients with this type of depression tend to have fewer suicidal thoughts but have more feelings of helplessness, pessimism and anxiety[53].

SOMATIZED DEPRESSION

This is more common than medical illness presenting as depression, especially in the current generation of elderly, who tend to somatize their psychological symptoms, having been brought up in a society which did not encourage the expression of emotion. Somatic symptoms in the elderly may represent physical illness, depression or emotional responses to physical illness. The somatic symptoms will need investigation, but depression, if suspected, should be treated.

Pseudodementia is a specific type of masked depression. One of the most important differentiating factors is that the severity of cognitive impairment fluctuates in depressed patients, remaining constant or worsening in the evenings in dementia. Depressed patients tend not to try to succeed in tasks, giving up with "I don't know" or "I can't". Demented patients will try, delighting in success but possibly becoming very distressed by failure—the so-called catastrophic reaction. Biological symptoms of appetite and weight loss, sleep disturbance and headache are typical of depression and not dementia. However, depression and dementia can coexist and the differentiation of the two conditions is not always easy. If in doubt, a trial of antidepressant treatment will help elucidate the diagnosis. The pathognomic symptoms of masked or somatized depression include:

1. Diurnal variation (symptoms usually worse in the mornings).
2. Mild impairment of cognitive processes and concentration.
3. Dysthymic mood changes.
4. Fatigue, feeling tired, lack of energy.
5. Sleep disturbance (waking up early and being unable to get back to sleep).
6. An anxious sense of failure or of "impending disaster".

LIAISON

Consultation-liaison psychiatry is becoming well established as an important specialty within general hospitals on both sides of the Atlantic. In an ideal situation, psychiatrists would attend ward rounds in the general hospital, particularly on rehabilitation wards, where prevalence of depression is high and the effect on delayed discharge well documented[42–44]. However, restricted resources prevent this: psychiatric morbidity is too high for a psychiatrist to see all the patients affected—his main role should be educational[54], only taking an active part in the management of more difficult cases. In many areas there is increasing development of specialist liaison nurses who are able to advise on diagnosis and treatment, reducing delay before assessments. The liaison nurse is likely to be more permanent than junior doctors on rotation and can often help a patient who refuses to see a psychiatrist or whose physician refuses psychiatric referral[55]. Liaison nurses can educate general nurses in the recognition of psychiatric disorder and can in turn encourage junior medical staff to institute appropriate referral or treatment. Their development and use has been compared with that of community psychiatric nurses[56].

The most common reasons for requesting a psychiatric consultation in a general hospital are[57]:

1. Diagnostic uncertainty.
2. Recognition of a gross psychiatric disorder.
3. Excessive emotional reactions, e.g. fear, anger, depression.
4. A patient's deviant behaviour disturbing ward or medical procedures.
5. Delayed convalescence, i.e. disability incompatible with observed pathology, relapse on mention of discharge.
6. Crisis in the doctor–patient relationship (e.g. refusing consent!).
7. Patient's admission of serious psychosocial difficulties.
8. Selection and/or preparation of patients, e.g. pre-transplant, cosmetic surgery.

It can be seen from the above list that the depressed patient, sitting quiet and withdrawn on the ward or in a home, may not be referred for a psychiatric opinion. In practice, only about 2% of geriatric patients are referred to the liaison services[58–60]. Suggested reasons for the discrepancy between liaison rate and psychiatric morbidity are[58,61]:

1. High prevalence of transient self-limiting psychiatric disease.
2. Physician's failure to recognize psychiatric disease[62]. Many studies have highlighted the unrecognized psychiatric problems on medical wards[61] and the underdiagnosis of major depression in particular has been well documented[63].
3. Medical and nursing staff may actively avoid questioning for psychological problems, due to fear of precipitating emotional distress with which they have not been trained to deal.
4. The low priority of psychiatric disease compared to physical, especially in a busy medical ward with acutely ill patients.
5. Poor access to, or dissatisfaction with, psychiatric services.
6. Physician resistance to psychiatric consultation[47], due to stigma or underestimating the severity or the potential for treatment.

Use of screening scales is appropriate for assessing depression in the physically ill: it is common, can be a difficult diagnosis and has significant morbidity and mortality if untreated. Care must be taken to differentiate between short-lived adjustment disorders, occurring as a reaction to the admission itself, or the crisis which precipitated it. Diagnosis in acute admissions should therefore include enquiry into symptoms before admission. If none can be elicited, the patient should be reassessed at a later date, either during rehabilitation or after discharge.

Screening scales serve a dual function[64–66]—they identify patients in need of further assessment and also serve as an educational tool if given by general staff during routine admission procedures. They emphasize the associated symptoms and signs of depression in the elderly, who may not show depressed affect and will deny feeling sad. It is important, however, that education about the treatment of depression goes hand in hand with education to recognize it, or the liaison services will be swamped.

TREATMENT

The fact that one can intuitively "understand" why the physically-ill elderly are depressed does not mean that it should be accepted as normal and treatment not attempted. Continuing physical illness is recognized as both a precipitant of depression and a poor prognostic factor, yet despite this, $\sim$80% of elderly general hospital patients are not depressed[42,67,68]. Successful coping mechanisms can prevent the emergence of clinical depression. Even in the terminal patient, depression or dysphoria can be relieved by euphoriants, such as oral or parenteral opiates, reducing the distress of patient and relatives[69] without significantly reducing the length of life remaining to the patient.

It is important that the diagnosis is not missed, as this condition usually responds well to treatment, at least initially, thus improving quality of life. Follow-up and early treatment of any relapses will further improve the prognosis. Increased self-esteem and ability to cope will reduce demand on families and possibly on services.

Even when the correct diagnosis is made, the depression may not be treated adequately, if at all: physically ill patients who are also depressed are more likely to be assigned to the "not to be resuscitated" group, compared with those elderly who are not

depressed. The lack of effort and motivation caused by depression may be regarded as "not trying" or "giving up" by nurses and rehabilitation staff, who withdraw from this group of patients for more emotionally rewarding non-depressed elderly subjects on the same ward.

The elderly as a group have approximately twice as many adverse drug reactions as younger adults[70]. They are frequently already on polypharmacy, so drug interactions are a real possibility. It is therefore important that physicians are advised and supported by the psychiatric services in the use of safe, well-tolerated antidepressants and other treatments to reduce the impact of this disease on both the individual and society.

Electroconvulsive therapy (ECT) is an effective treatment of depression[71,72]. The response to treatment in older people is better than in the young[73,74]. With the increasing safety of anaesthesia, very few patients, even those with severe physical disease, are unable to tolerate a course of treatment. It is more rapid in effect than medication alone, but the improvement is rarely sustained unless antidepressants are also given to prevent relapse.

A review of psychological treatments in chronic illness[75] found very little empirical evidence of benefit when therapeutic interventions were applied indiscriminately. However, some evidence was found to show benefit in patients with somatization disorders rather than physical illness, and also that brief interventions following the onset of acute physical illness reduced longer-term psychological morbidity. A suggested general approach to the treatment of physically ill depressed patients is:

1. Investigate and give appropriate treatment to all physical problems, either curative treatment or to minimize persistent morbidity. Explain the illness, treatment and prognosis to the patient in as much detail as he/she wishes. Make sure the explanation is understood and repeat as often as necessary.
2. Give general social support, e.g. home help services, financial assistance if relevant, or residential or nursing home care.
3. Give psychological support—encouragement, continued interest in the patient, e.g. outpatient follow-up. Support groups are often beneficial for chronic conditions such as rheumatoid arthritis, Parkinson's disease, etc.
4. Consider antidepressant therapy if the symptoms are sufficiently severe that they would be considered to warrant medication if seen in a patient without physical problems. Monitor the response to treatment; this may take 7–8 weeks[76]. If no response is seen to a therapeutic dosage of antidepressant, consider a trial of an alternative antidepressant or adjunctive treatment, or specialist referral.

PROGNOSIS

Little is known of the prognosis of psychiatric disorder identified in the medical setting[77], except that concomitant physical illness is a poor prognostic factor. Psychiatric disturbance often persists[78–80], especially in patients with a previous history of psychiatric disorder. Those with affective disorder on admission have increased mortality and make greater demands on medical, social and psychiatric services[77,81].

In one series of consecutive acute medical admissions[80], fewer than 45% of those patients with concomitant depression had received antidepressants at all, 20% had been given benzodiazepines, and less than 25% had been treated for more than one week. The authors concluded that an effective treatment for depression in elderly patients needed to be found, with widespread education of geriatricians in the diagnosis and treatment of depression.

In psychiatric patients, relapse has been linked with supervening physical illness[82]. The presence or development of cerebral or any other irreversible physical disorder indicates poor future mental health in the great majority of patients, as well as the likelihood of early death[83].

The prognosis of the physical illness, for both morbidity and mortality, is also inextricably linked with that of the depression. Increased mortality from physical illness, especially cardiovascular disease, has been reported[84,85]. This excess of deaths is significantly associated with groups who have been only partially treated, e.g. have not responded to antidepressants[86], especially in older men[87].

Explanations for the apparent association of physical illness with poor treatment outcome might include[88]:

1. Age as a confounding factor—most of the trials of treatment in the physically ill are in the elderly.
2. Medically ill patients may be given inadequate doses of antidepressants because of problems with side effects or over-cautious physicians.
3. Different subtypes of depression exist, some medication-responsive, some not. Organic mood disorder (depression induced by physical illness or a specific organic factor) has been shown to have a worse prognosis at 4 year follow-up[89].

The prognosis of depression in the physically ill elderly is therefore dependent on accurate diagnosis, intensive treatment, follow-up and early treatment of any relapses[82,84,90]. Increased self-esteem and ability to cope will reduce demand on families and possibly on services. No studies have yet convincingly identified predictors of response in physically ill populations, although pre-existing depression prior to admission with physical problems appears to predict persistent depression, rather than if the depression develops in hospital[78,91].

SUICIDE

Suicide is the most dramatic of poor outcomes, and the elderly are over-represented in suicide statistics. Although the elderly are less likely to attempt suicide, they are more likely to complete it[92,93]. The presence of physical illness, especially if associated with chronic pain and disability, increases the risk; elderly men living alone are at the highest risk. The individual's adjustment to ill-health and his associated feelings of hopelessness and demoralization are obviously important[94]. Many elderly suicide victims are suffering from their first episode of major depression, which is typically only moderately severe but the diagnosis is missed[95], and the potential for recovery following intervention therefore lost.

Depression has been linked to decreased compliance and to voluntary refusal of life-saving essential medical treatments[96,97]. This may reflect either conscious or unconscious suicidal motivation.

SERVICE IMPLICATIONS

It is important to note that the aging population itself is growing older, with large numbers of very old individuals. It is this old-old group who have the highest physical and psychiatric morbidity and who make the greatest demands on services.

Undergraduate teaching programmes must be tightly integrated in order for students to develop a holistic approach to the elderly, together with an understanding of the psychosocial and economic factors that will affect presentation and treatment. Joint postgraduate meetings between the two specialties are becoming more common and should be encouraged, each maintaining their separate identities and training but working closely together in clinical practice.

Interdisciplinary research continues to grow in amount, but is mostly directed at psychiatric problems on medical wards. Little seems to be researched in the other direction, medical illnesses on psychiatric wards. All research is obviously relevant to both specialties and in practice helps to strengthen links between them.

CONCLUSION

Depression in the elderly physically ill can present a difficult problem of diagnosis. To avoid the increased morbidity and mortality of untreated depression, it is necessary to be aware of the possibility of depression causing somatic symptoms, the physical illness causing depressive symptoms, or both conditions coexisting, and then to treat the depression effectively. Close liaison between psychogeriatric and geriatric teams is thus very important if this vulnerable group is to receive the correct diagnosis and treatment.

Physical Illness and Depression: a Number of Conundrums

M. Robin Eastwood

Formerly at St Louis University Medical School, MO, USA

One of the clinical conundrums in modern medicine is that psychiatric patients complain frequently in somatic terms and yet *truly* suffer from an excess of physical illness[1]. In a review conducted as part of a European Science Foundation Study (EMRC), Hafner and Bickel[2] concluded that "Studies of mortality in mental patients have shown that . . . these patients still have an excess risk for natural causes of death which is not restricted to patients or to certain diagnostic groups . . . However, the evidence for *specific* associations between psychiatric diagnosis and natural causes of death is not yet conclusive". In a commentary, Rorsman[3] said that two out of three major *longitudinal* studies indicate, at least in men, that mental illness strongly affects the risk of dying from natural causes. Murphy *et al.*[4], from the Stirling County study, found death to be significantly associated with affective, not physical disorder, and depression, not anxiety. Rorsman *et al.*[5], from the Lundby study, found that psychiatric patients have a significantly increased natural death risk, and *untreated* psychiatric males in particular.

An issue of the *International Journal of Geriatric Psychiatry*[6] dealt with physical illness and depression in the elderly. Burvill, from Australia, pointed out that physical illness worsens the prognosis of depressive illness in the elderly. Lindesay, from the Guy's/Age Concern Survey in the UK, found that 70% of depressed subjects reported one or more serious physical problems. Sadavoy *et al.*, from Canada, found that about 75% of the elderly with chronic physical illness had cognitive impairment and 35% were depressed. There was a significant correlation between cognitive deficit and depression.

Eastwood and Corbin[7], in a review of the connection between depression and physical illness in the elderly, addressed another conundrum. While physical disease increases with age, depression may not do so. In community surveys of the elderly, fewer than 25% are disease-free and over 50% have at least one activity-limiting disorder[8]. While the findings are disputed, depressive illness apparently declines with age, while depressive symptoms increase. Snowdon[9] argued that depressive symptoms and syndromes are difficult to distinguish in the medically ill. He thought that, since conditions which significantly correlate with depression, such as dementia, physical disability, physical illness, bereavement and so on, increase with age, then so must depression. Recently, Mann[10] argued that, "if other depressive, diagnostic terms are included—'minor depression', 'subthreshold syndrome' or 'depressive symptoms'—then the total rate of depression is, in fact, higher than in the younger age groups". The truth probably lies in some complex multivariate relationship. Notwithstanding, there are some fascinating and relatively direct relationships, such as stroke causing depression[11] and grief causing increased coronary heart disease[12]. Fascinatingly, Glassman and Shapiro[13] consider that we have reached the point where we can state that depression is an independent risk factor for coronary heart disease. While taking this as an interesting postulate, it has to be remembered that atherosclerosis could be a cause of both depression and heart disease. At this stage we do not know whether intervention with antidepressants would reduce the risk of depression on heart disease.

Finally, as Hafner and Bickel suggest, prospective studies with disease registers will help sort out general and specific relationships and direct and indirect risk factors, and help confirm Rorsman's statement, that this all means that psychiatry is a branch of medicine.

Depression after Stroke

Peter Knapp and Allan House
University of Leeds, UK

It is now accepted that stroke patients have high rates of all types of depressive disorder. However, estimates of the prevalence of depression within the first month of stroke vary greatly[1,2], according to the type of measure used and the way the sample was derived. The consensus seems to be that 20–25% of patients after stroke will suffer a major depressive disorder within the first month[3]. Rates of depression later on after stroke are less certain, because of patient attrition in studies. Depression remits in some patients, while in others it persists: one study reported that 50% of those depressed within 3 weeks of stroke remained depressed 1 year later[4]. Depression not only affects quality of life: patients with depression after stroke may be at greater risk of mortality[5], cognitive impairment[6] and poorer functional or social recovery[7,8].

There are claims that post-stroke depression is a distinct subtype[9]. There is little unequivocal evidence to support this claim, since psychological and biological symptoms reported by patients are found in depression seen in non-stroke patients[10]. What does appear to be distinctive is the increased prevalence of persistent crying (emotionality) among stroke patients. A small number of patients suffer *pathological laughing and crying*, a syndrome which is probably neurological in origin, in which emotional expression arises after minor provocation that often appears meaningless[11]. A more common syndrome, *emotionalism*, is also characterized by increased tearfulness, but is more complex. The emotional episodes are provoked by meaningful stimuli, but the crying is characterized by a lack of warning and control. There appears to be a psychological component to its origin[12]. *Emotionalism* is associated with an increased risk of depression[13], but patients with emotionalism may be at greater risk of psychological problems not explained by concurrent depression[14]. This syndrome is probably under-recognized.

Reaching a diagnosis of depression after stroke can be complicated by the presence of problems such as communicative or cognitive impairment[15]. Patients with expressive communication problems can often be assessed by the careful use of closed questions. The assessment of those with receptive communication problems or significant cognitive impairment is much more complex: a non-language-based assessment of depression shows promise but is insufficiently reliable in its present form for accurate diagnosis[16]. The diagnosis of depression might also be confused by facial palsy and a disturbance of speech prosody (rhythm in speech), both of which are relatively common after stroke and which give the patient the appearance of a person with depression[17]. The dexamethasone suppression test is not sufficiently sensitive to be used as a diagnostic tool[18].

The high rate of depression reported in some stroke research has led to the suggestion that the neurological damage is a key factor in its aetiology[19]. As a result, many studies have attempted to link depression after stroke with lesion location. A series of studies proposed, first, that patients with left hemisphere lesions were at greater risk of depression[20], and later, that those with left anterior lesions were at most risk[21,22]. Other researchers[23–25] have not replicated these findings, suggesting that patient sampling and the timing of assessment might explain the differences.

Even if lesion location is associated with greater risk of depression, the context of this relationship is important. First, it is clear that stroke patients with all sorts of lesions can suffer depression[9], so factors other than lesion location must also be at work. Second, stroke location is extremely varied[26], so those with any particular lesion (such as left anterior lesions) will be a minority of patients, making the attributable risk due to any one type of lesion small. Last, although the rate of depression in stroke patients is higher than in age-matched non-stroke controls, it is about the same rate as in patients with non-neurological disabling illness[17,27], suggesting that non-neurological factors are as important. Relevant non-neurological aetiological factors are likely to include the threat of disability and a sense of loss.

That psychosocial factors are likely to be relevant to both the onset and persistence of depression has been illustrated in several studies. For example, one study found that depression at 4 months after stroke onset was commoner among those with greater disability, those who were divorced and those with higher pre-stroke alcohol intake[24]. Depression is more likely in those patients who perceive their stroke as a greater threat, and in those who have fewer psychological resources to deal with that threat.

Patients with depression after stroke might be considered for pharmacological or psychological treatments. Two small trials showed beneficial effects of antidepressants, although both studies had high rates of patient dropout[28,29]. The evidence for treating emotionalism with antidepressants is rather stronger—both tricyclics and SSRIs have been shown to reduce the frequency of crying episodes[30–32]. There is no good trial evidence to draw upon in assessing whether psychological interventions are effective in treating depression after stroke[33].

Some services aim to intervene in an attempt to prevent the onset of depression after stroke. A recent small trial found that patients prescribed mianserin as a prophylactic had greater improvement in depression scores, but the drug did not reduce rates of major depression 6 months after stroke[34]. A variety of preventive psychosocial interventions have been evaluated in clinical trials. The interventions, including education, leisure therapy and specialist stroke nurse visits, have shown no effect in reducing the prevalence of depression. However, many of the trials are small and imperfectly designed, so the conclusion should be lack of evidence, rather than evidence of no effect[35].

Our own recently completed study suggests that a brief psychological treatment (problem-solving therapy) may be beneficial[36,37]. Patients who received therapy visits from a community

psychiatric nurse had lower rates of depression 6 and 12 months after stroke than those in the treatment-as-usual group, and lower scores on a measure of psychological distress at 12 months. This finding is encouraging, since it shows that a brief, structured psychological intervention is beneficial to patients after stroke, albeit in a sample selected to participate in a clinical trial. There are disadvantages to psychological management: it may be difficult to implement in patients with significant speech and cognitive impairment[38], and some patients find psychological treatments unacceptable, both before and after the treatment has started.

In summary, depression after stroke is common, and its causes are probably multiple—biological, psychological and social—as is the case in other physical illnesses. The evidence for benefit from antidepressant drugs is surprisingly poor, considering their problematic side effects and how widely they are prescribed. The potential for psychological therapies has been underevaluated, which is a deficit that badly needs correcting. Pending further research, clinicians will need to rely on evidence from other areas of physical medicine to inform their treatments.

Treatment of Depression in Older People with Physical Disability

Sube Banerjee[1] and Florian A. Ruths[2]

[1]*Institute of Psychiatry, London, and* [2]*Queen's Resource Centre, Croydon, UK*

THE CASE FOR TREATMENT

As discussed elsewhere, depression is the most common mental disorder in the over-65s, with a prevalence of 13–16%[1,2]. It is a serious disorder, associated with profound decrease in quality of life[3], suicide[4], non-suicidal excess mortality unexplained by physical disorder[5], and excess health and social service use not explained by disability[6,7]. Depression in the elderly also has a substantial financial impact, costing community health and social services in the UK in excess of £1 billion/year in depression-dependent service use[8].

Depression in the elderly therefore has a serious impact on the people suffering from it, their families, and health and social services. Despite this, it is a consistent finding that few older people with depression receive appropriate treatment from primary or secondary care services. Only 10–20% of cases of depression are prescribed antidepressants[7,9,10], with no evidence of their receiving non-drug treatment instead. The reasons for this lack of appropriate action is unclear, some implicating low GP recognition[11] and some a lack of action when depression is found[12]. Whatever the mechanism, there are clear discontinuities on the path from contact, through recognition to action[13].

Older people with physical illness or disablement are a high-risk group for the development of depression[14]. One particular high-risk group consists of those maintained at home, receiving social service home care; 26% of these have clinical depression[15] and, adjusting for age and gender, they have twice the prevalence of depression of the general elderly population, with a four-fold excess of the most severe forms[7]. One possible determinant of therapeutic inactivity may be a perception that depression is untreatable in frail older people, and an important element in clinical behaviour change is evidence of the effectiveness of intervention. Meta-analyses suggest that antidepressants have efficacy in the treatment of depression in those with a variety of physical illnesses[16], with the same sort of effect sizes as those observed in the physically well. However, the evidence for the effectiveness of treatment for depression in the disabled elderly is sparse, since they are often systematically excluded from drug trials[17]. We therefore completed a randomized controlled trial (RCT) to investigate whether depression in home-care clients was treatable by community old age psychiatric services[18].

THE EFFECTIVENESS OF OLD AGE PSYCHIATRIC COMMUNITY TEAM INTERVENTION

Sixty-nine cases of depression were identified by screening the home-care population and randomly allocating them to treatment as usual by their GP, or to treatment by the local old age psychiatric community team, with blind follow-up at 6 months. There was a powerful treatment effect, with 58% of the intervention group recovering, compared with only 25% of the control group (adjusted odds ratio 9.0 [95% CI, 2.1–41.5]). The intervention was pragmatic, involving the multidisciplinary team formulating an individualized management plan and this being implemented by a research worker working as a generic team member. Analyses were carried out on an intention-to-treat basis.

This study's results suggest that therapeutic nihilism, based on an assumed poor response to treatment in the disabled elderly, may not be justified. There are similarly encouraging data for the general population of older adults with depression from GP practice-based community psychiatric nurse intervention[19,20] and nurse-based outreach programmes[21]. However, all these interventions are complex and delivered by secondary care services, and are therefore not directly transferable into primary care settings. Given that there may be 500 000 disabled older adults with clinically significant depression in the UK alone at any one time, secondary care intervention for all is not feasible. It would also be unnecessary if depression in the disabled elderly were to be managed successfully by primary healthcare teams. These are questions which require further research.

Elements of Effective Intervention

The dysjunction in the system of care from disorder to recognition to action has been outlined above. What, therefore, does this mean for the formulation of effective interventions for older people with depression, and where might change be focused best to achieve maximum health gain? These questions can be addressed by considering the pathway from depressed state to resolution, using the data we have for disabled elderly home-care recipients.

Figure 1 presents a simple model. In it, the outcome of depression depends on two parameters, the natural history of the disorder and the effectiveness of intervention. The extent to which an intervention is deployed depends on there being both recognition and action. In Figure 1, the data from the home-care studies are applied to a standard population of 100. In the first stage, the current 15% rate of any active management for depression in this population[7] is applied to divide the group into a "treated" and a "not treated" group. The second stage is to apply the spontaneous recovery rate of 25% to the "not treated" group and the 60% recovery rate from our RCT with active management to the "treated" group[18]. When these filters are applied, only

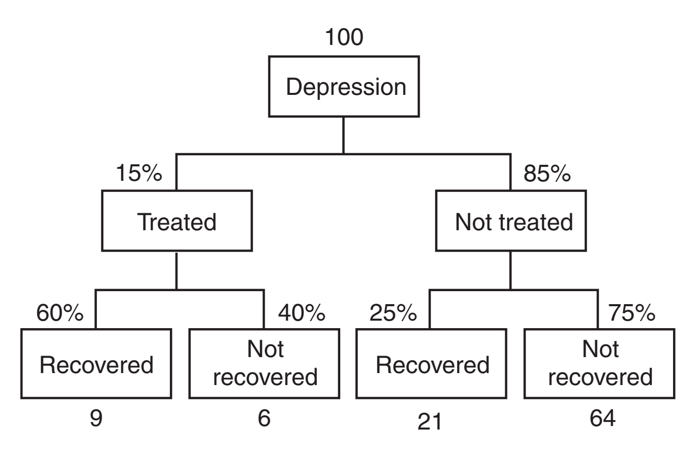

Figure 1

30 of the 100 recover (only nine in the "treated" group and 21 spontaneously recovering in the "not treated" group).

Where, then, should effort be focused to address this situation? The spontaneous recovery rate will be fairly resistant to change and the gain from trying to improve the efficacy of treatment would appear to be relatively limited. For example, an increase in the efficacy from 60% to 80% (an increase unlikely to be possible at present) would only increase the numbers recovering by 3 to 12 in the "treated" group. What is clear from Figure 1 is that the main determinant of the poor population outcome is the low rate of recognition/active management. This would suggest that resources should be focused on increasing the proportion that enter the "treated" group, since there is the greatest scope for improvement at this point and any benefit at this stage will cascade down the system. So, if the proportion "treated" were to be raised by 20% to 35%, the numbers recovering in the "treated" arm would rise to 21 (with 37% recovering overall). If only half of the population of people with depression were identified and treated, then this would rise further to 30 (with 43% recovering overall) and a 75% treatment rate would yield 45 recoveries (51% overall).

CONCLUSIONS

These data demonstrate that, on a population level, there is likely to be far greater health gain from attending to the processes of recognition of depression in the elderly, and of linking this recognition to action, than there is by simply focusing resources on attempting to develop interventions with greater efficacy. This is supported by the emerging evidence base, which endorses the feasibility, acceptability and effectiveness of screening for and treating depression in older adults in the community[18–21].

Acute Management of Late-life Depression

Veronica Gardner and David C. Steffens
Duke University Medical Center, Durham, NC, USA

The acute management of late-life depression may require hospitalization, both for accurate diagnosis and for effective treatment. Ambulatory management is frequently favored because of rising hospital costs in a managed care environment. However, the elderly present special challenges that may require that diagnosis and/or treatment be undertaken in a hospital setting. The hospital provides an environment for the monitoring of symptoms for accurate diagnosis and proper personnel for regular and accurate treatment administration. Several factors may interfere with both accurate diagnosis and effective treatment on an ambulatory basis[1], including underlying chronic medical illness, pain, neurodegenerative changes, dementia, adverse life events, inadequate family support, secret self-medication, substance abuse, bereavement, interpersonal conflicts and social isolation of the elderly patient.

Actually, the elderly patient who is cognitively intact may be reliably managed on an ambulatory basis and can be instructed about medication side effects. Similarly, the more impaired elderly patient who has adequate social support for observation and medication management may only need the community support of a visiting psychiatric nurse, assuming one is available. Varying levels of care are also implemented in the hospital environment. A patient may have the usual care of routine monitoring or may have more intense one-to-one monitoring if he/she is an imminent risk to him/herself or others.

As a general rule, the more the physical and psychiatric impairments and fewer psychosocial resources, the greater the need to hospitalize for accurate diagnosis and effective treatment. When deciding safe and effective management, the following factors favor hospitalization: poor or unstable physical health, high suicide risk, impaired judgment and reality testing, likelihood of poor compliance, impaired cognitive functioning, lack of social support, and severe anorexia and weight loss.

CO-MORBIDITY OF PHYSICAL ILLNESS: THE INTERFACE OF PRIMARY CARE AND PSYCHIATRY

Accurate diagnosis is a prerequisite for effective treatment. Elderly patients with depression present to their primary care physicians and psychiatrists in a complex manner, and signs and symptoms of physical illness and depression overlap. Even the normal effects of aging may cause diagnostic difficulties and restrict treatment options. Many primary care physicians diagnose and treat late-life depression without referral. However, those patients who fail two or three trials with antidepressants, usually selective serotonin-reuptake inhibitors (SSRIs) or newer agents, are commonly referred to a psychiatrist for further management. These patients represent a treatment challenge and may require complex medication regimens that are more successful with hospitalization. Primary care physicians also refer for the following reasons: suicidality, co-morbidity with substance abuse, dementia, anxiety disorder, presence of psychosis (delusions, hallucinations), catatonia, bipolar disorder, and inability to tolerate antidepressant treatment[2,3]. Such patients often need to be managed in the hospital.

Depression is often co-morbid with other physical diseases. Approximately 80% of older adults suffer from at least one chronic health problem[4]. The prevalence of co-morbid depression may be up to 30% in stroke patients, 18% in myocardial infarction patients, 51% in patients with hip fracture, and 50% in patients with chronic pain[1]. Existence of an undiagnosed and untreated depression with these illnesses leads to higher disability[5]. The diagnosis of depression with certain illnesses is complex, and the hospital environment provides the necessary monitoring and support staff when complicated medication changes are required.

For example, a patient with cardiovascular disease may present with decreased energy and apathy. Determining whether this is caused by a compromised cardiac status, a medication side effect, or is actually a symptom of depression may be difficult without hospitalization, close monitoring and various medication trials. Formerly, hospitalization was favored for the initiation of tricyclic antidepressant therapy in elderly patients with unstable cardiac disease. First-line treatment with SSRIs is now available and proved safe for use in cardiac disease[6].

Co-morbid neurological illness is also common in geriatric depression. Patients with depressive symptoms following a cerebrovascular accident also present a diagnostic challenge. There may be communication difficulties or other neurologic abnormalities. Depression may be diagnosed only by the report of the nursing staff and family, who observe apathy, irritability, tearfulness and weight loss[7]. Patients with Parkinson's disease may develop an affective illness or psychosis, which may be secondary to treatment with L-dopa. Hospitalization may be required for medication changes if outpatient support is inadequate.

Severe anorexia, weight loss and refusal to eat are indications for hospitalization for safe and effective treatment[8,1]. Poor oral intake commonly accompanies severe depression, but it may also result from a variety of medical conditions. For example, individuals with active rheumatoid arthritis may experience insomnia, fatigue and poor appetite equally from their physical illness or an associated depression[9].

SUICIDE RISK AND THE DECISION TO HOSPITALIZE

Suicidality is the most common reason for psychiatric hospitalization. According to Jacobson[29], three goals for inpatient treatment are: (a) the preservation of life and safety; (b) the elimination of

suicidal intent and ideation and treatment of underlying disorders; and (c) the improvement of intrapsychic capabilities, personal factors and psychosocial circumstances to facilitate coping after discharge and decreasing risk of the return of suicidality. However, implementation of these treatment plans is predicted on the initial detection of suicidality.

Careful assessment of suicide risk in depressed older adults is thus vital. The elderly are less likely to have made a prior suicide attempt, but they consistently demonstrate a higher rate of completed suicides[10]. The ratio of attempted to completed suicides decreases with age from 200:1 in young adulthood to 4:1 in the elderly[11]. The higher rate is due primarily to the increased frequency of deaths among older, White males. In 1992, persons 65 and older accounted for 13% of the population but almost 20% of suicides. Even though the frequency of suicide has increased among older persons in the USA, the prevalence is not as high as that of other industrialized societies[10].

Recognition of variables such as gender and race may influence management decisions. Risk factors for suicide in late life include increased age, with the highest prevalence of suicide of persons older than 85[10]. Also, being male, White, single, separated or divorced, or widowed are risk factors for suicide. Other risk factors implicated in late-life suicide include: a positive psychiatric history (especially depression and alcohol abuse and dependence); physical illness and functional disability (especially diseases of the central nervous system, malignancies, cardiopulmonary conditions, and urogenital diseases in men); previous suicide attempts; psychological factors (i.e. hopelessness); social factors (stressful life events, e.g. bereavement); and biological susceptibility (dysregulation of the hypothalamic–pituitary–adrenal axis or the serotonin system).

Most older people who commit suicide have seen a primary care provider within 30 days of death[11]. This observation stresses the need for collaborative efforts with primary care physicians and the need to make careful assessment based on risk factors.

A number of assessment guidelines have been developed to aid in the evaluation of potentially suicidal patients. A four-item screen for identification of suicidal ideation among general medical patients was developed by Cooper-Patrick *et al.*[12].

1. Have you ever felt that life is not worth living?
2. Have you ever thought of hurting or harming yourself?
3. Have you considered specific methods for harming yourself?
4. Have you ever made a suicide attempt?

This four-fold layered approach to assessment is useful in obtaining the necessary data without disrupting the therapeutic relationship. If the answer to the first or second question is negative, then the inquiries can cease and the older person may be considered at low risk for suicide[10]. This approach has advantages over other assessment tools, which usually suggest one question to be asked to assess suicidal risk.

DELUSIONS AND LATE-LIFE DEPRESSION

Accurate diagnosis and effective treatment of depressed elderly patients with delusions can be hindered by their impairment of reality testing. Their sometimes well-organized and complex delusions may make them distrust medicine and the physician who prescribes it. This disorder is less frequent in the community and more prevalent in the hospital setting[13,14]. Accurate diagnosis is necessary, as some studies have suggested that the depression is more severe[14,15] and it has been associated with suicide[13]. Varying reports also demonstrate decreased cognitive functioning and social functioning among patients with delusional depression[16]. These patients are best treated in the hospital. They cannot be relied upon to take accurate doses of medications. Effective pharmacologic treatment for delusional depression requires combination treatment with high-dose antipsychotic medication and antidepressants[15]. ECT has been successful for the treatment of delusional depression[17–19] and can be performed on an outpatient basis only with adequate social support.

COGNITIVE DYSFUNCTION AND LATE-LIFE DEPRESSION

A full discussion of how depression is distinguished from dementia is given elsewhere in this book. To summarize, diagnosis is difficult because several symptoms of depression and dementia overlap, such as a flattened affect, psychomotor retardation and presence, at times, of delusions[20]. Delusions are reported to occur in up to 40%[13] of Alzheimer's disease patients, although they are described as transient and less organized than in delusional depression[13]. Major depression occurs in over 20% of patients with Alzheimer's disease and vascular dementia[4,21]. This significant co-morbidity may lead to profound disability[22].

The diagnosis of depression in dementia usually requires the input of family members or nursing personnel[23,24]. The patient with cognitive dysfunction and impaired reality testing cannot reliably report symptoms, take medication accurately, or reliably report side effects.

Dementia with depression and behavioral disturbance is frequently too complex to treat on an outpatient basis. These patients may even require involuntary commitment. Aggression may be verbal or physical. Aggression and agitation in dementia may be as high as 50% in the outpatient population[25,26]. The hospital environment is the only setting with constant monitoring to make an accurate diagnosis, contain behavior and monitor medication.

The reversible cognitive impairment that may accompany depression also increases disability[27]. With treatment, the cognitive impairment usually improves. However, these patients are at higher risk to develop an irreversible dementia in the future[28].

CONCLUSIONS

The patient with late-life depression frequently presents in a complex manner that may require hospitalization. Accurate diagnosis and treatment of these patients is essential to prevent disability, caregiver burden and nursing home placement. Confusion, suicidality and aggression represent psychiatric emergencies in the elderly and may require hospitalization for effective management.

Electroconvulsive Therapy (ECT)

David G. Wilkinson
Moorgreen Hospital, Southampton, UK

Those who decry it in the elderly are sentimental and ill-informed. ECT for suitable patients not only relieves intolerable anguish but saves lives (Brice Pitt[1]).

Despite continued opposition to its use, ECT remains a fundamental tool in the armamentarium of the psychiatrist treating the severely mentally ill. There have now been thousands of papers and articles published concerning its use and we have a wealth of accumulated wisdom, and yet the controversy continues[2].

In geriatric psychiatry there is no controversy: papers continue to confirm that in the elderly ECT is an effective treatment for severe affective disorders[3–6] and is the treatment of choice in severe delusional depression[7–10]. It is safe, despite the likelihood of multiple system disorders and medications[11]. It is well tolerated, if not always well liked[12], but does sometimes exacerbate confusion. There is no convincing evidence of brain damage or even of lasting memory impairment, particularly if brief pulse right unilateral ECT is used[13]. ECT should be considered in every patient who has either failed to respond to other treatments, or who is suffering intolerable distress, or who may die through inanition or dehydration as a result of his/her depression. It is probably for these reasons that ECT continues to be used six to seven times more frequently in the elderly than in their younger counterparts[14]. The fact that in the USA it has also been shown that early use of ECT reduces inpatient costs may have also been an influential factor in its greater use[15].

INDICATIONS

Studies on the efficacy of ECT, which have largely been conducted on younger patients[7], all emphasize that ECT appears to be more effective than placebo, single-drug therapy and tricyclic/neuroleptic combinations, and that patients with more florid symptoms of recent onset fare best[7,16–18]. Experience with the elderly would confirm these findings. Indicators of response are perhaps less clear in the elderly, with some authors finding psychomotor disturbance and psychosis a positive predictor of response[10] and others suggesting that patients without these features can also do well[19]. That the classic distinction between neurotic and psychotic depression appears less helpful in this group as a predictor of good response is nothing new. Post[20] in 1976 stressed the practical irrelevance of any subclassification of elderly depressives, as he found that ECT rendered severe psychotic depressives fit for discharge only slightly more often than neurotic depressives. The presenting picture of hysterical illness, hypochondriasis or other apparent neurotic illness may well be caused by an underlying functional psychosis, often depressive in the elderly. More recently, in a study of 163 elderly patients given ECT, it was found that 27% had predominantly neurotic depressive features and yet had a good response to treatment[3]. In fact, in the study by Fraser and Glass[21], psychic anxiety, along with the more expected features of short duration, severity of illness, guilt and agitation, was one of the symptoms correlated with a favourable response to ECT, whereas the typical endogenous features of late insomnia and diurnal variation in mood were not. Treatment resistance in the elderly will respond to ECT, although not as well as non-resistant patients[22]. However, they do respond better to ECT than SSRIs[18] and Flint[5] found that ECT was significantly superior to tricyclic/neuroleptic combinations, even when the former had been augmented with lithium. A pragmatic consensus would suggest that in the elderly a trial of ECT is indicated in any depressed patient who might otherwise be regarded as a treatment non-responder, and if the illness is severe and of short duration there is likely to be a good response, regardless of the presenting symptoms. If the illness has been present for some time, or even years, it still may respond if there is a clear history of a change for the worse in the patient who had previously maintained a stable personality and had coped normally with the vicissitudes of life. Prolonged or abnormal bereavement reactions with marked depressive features not responding to antidepressants or talking therapies may need to be treated with ECT before psychotherapy or counselling can be effective. ECT may need to be given within a few months of the loss if hopelessness and suicidal ideation suggest a risk to life, and should not be withheld due to the feeling that the patient must work through his/her grief naturally, as he/she may never get that chance.

Mania is another indication for a trial of ECT[23], particularly in the elderly, where neuroleptics may fail to control the symptoms and yet produce unsteadiness, postural hypotension or falls, and lithium may not be tolerated due to toxicity problems.

Paraphrenia will often respond to ECT[24], although this is more likely if there are obvious depressive symptoms or delusions.

ECT is certainly useful in the depressed patient with Parkinson's disease, as the motor symptoms will improve as well as the depression, and indeed, some authors advocate ECT as the treatment of choice for certain stages of Parkinson's disease, whether or not depression is a major problem[25,26]. I have given daily ECT with excellent results to a parkinsonian patient who had developed severe paranoid delusions. His refusal to accept his medication rendered him rigid and immobile with pressure sores, he needed intravenous fluids and nasogastric feeding until he had four treatments, whereupon his physical and emotional improvement was dramatic.

Fogel[16] suggests that ECT might be more readily used in the elderly if we were more objective about its virtues as compared with the severe side effects often associated with neuroleptics, which are quite readily used in the agitated elderly patient. Extrapyramidal effects were usually the limiting factor but are not so noticeable with atypical neuroleptics. However, he postulates that the demented patient who is very agitated and screaming might suffer less indignity and fewer side effects if treated with ECT, rather than tranquillizers, as the patient may have an underlying affective disturbance manifest only by the agitation and negativism that one often sees in this condition.

CONTRAINDICATIONS

There are no absolute contraindications, only relative risks, relative that is to the morbidity and mortality of untreated depression. The limiting factor is whether the patient is fit for the light anaesthetic that ECT requires. The majority of risk factors are therefore associated with the cardiovascular system. Many people are denied treatment due to irrational caution. For example, pacemakers are not barriers to treatment; the bodily tissues, being highly resistant, prevent the ECT stimulus from reaching the pacemaker in any case. The patient should remain insulated from the ground, however, to prevent the unlikely event of the current leaking to earth and being conducted down the pacemaker wire to the heart. Equally, myocardial infarction is not a contraindication to treatment if the depression is so severe as to threaten life; in less severe cases, an interval, governed by sentiment rather than science, of 4–6 weeks is usually left. The risks are greatest during the first 10 days post-infarct, and probably negligible after 3 months. I have treated a patient with treated hypothyroidism who had two prosthetic heart valves, was therefore on anticoagulants and had a pacemaker, with no special precautions or untoward effects. Patients with osteoporosis or with recent femoral neck fractures can be treated, provided an adequate muscle relaxant is given. Stroke is certainly not a contraindication, and ECT given as soon as 1 month after does not present a major risk to patients. There is now a growing body of literature attesting to the usefulness of ECT in treating post-stroke depression[27].

The case of deep venous thrombosis (DVT) is less clear. I have given ECT to a patient who had a DVT in his calf during his depressive illness, once he was adequately anticoagulated. In fact, the risk of pulmonary embolism seems, in my practice, greater in the dehydrated immobile depressive than in those receiving ECT. Arterial hypertension is often regarded as a contraindication, as blood pressure is well known to rise during ECT. This can sometimes be controlled and the pressor response avoided by using sublingual nifedipine or short-acting β-blockers shortly before treatment[28]. Chronic glaucoma is another condition in which ECT causes fewer problems than tricyclic antidepressants; in fact, intraocular pressures are said to reduce ECT[29]. Insulin-dependent diabetes is a condition, like Parkinson's disease, which alters during ECT. Insulin requirements may decrease quite substantially during the course of ECT, so more careful monitoring of blood glucose levels is needed. It is also necessary to avoid hyperglycaemia prior to treatment, which may significantly raise the fit threshold, and the timing of ECT administration may need consideration to prevent undue fluctuations in diabetic control. Transient asystole occasionally occurs, for some reason less frequently in the old-old, but it is not of any consequence and need not prevent further treatments[30,31].

Epileptic patients on anticonvulsants should not stop their medication during ECT, as that might increase the risk of status epilepticus. However, they may need higher than usual electrical dosages to produce an adequate response.

It is interesting that the seizure during ECT is invested with great powers of harm compared with epileptic seizures *per se*, which can of course occur in patients with any disease or at any time and seldom result in death. It seems understandable, then, that a seizure in the controlled conditions of the ECT room is probably even less likely to result in fatality. There is, of course, a mortality rate associated with ECT but, as noted by Fink[32], the treatment rate of 0.002% compares favourably with the rate for anaesthetic induction alone (0.003–0.04%).

ADMINISTRATION

The responses of senior psychiatrists to the process of ECT vary from those who simply prescribe six treatments and leave the administration to the newest recruit, who has often had no training at all, to those surgeons *manqués* who may overstate the risks and precautions in order to increase the perceived risk of their jobs. Clearly, the ideal path lies somewhere between, but nearer the latter than the former! ECT is the only psychiatric treatment in the elderly that involves significant medical intervention with general anaesthesia, and as such, the psychiatrist should have a clear understanding of what he/she is prescribing and regular involvement in its administration. As much attention should be paid to the prescription of ECT as to any other prescription.

A clear decision as to whether bilateral or unilateral electrode placement is wanted should be made; the ECT record sheet should be reviewed to ensure that an adequate convulsive response has occurred without excessive stimulus; treatments should not be in blocks of six, but, provided that the illness is one with a good prognosis, treatment should be continued until the expected degree of improvement is obtained, whether that is after three or 23 treatments.

There is no evidence that the habit of giving one or two extra ECTs after full recovery is effective in preventing relapse[33]. The decision to give unilateral or bilateral ECT in the elderly is made easier by the fact that high dose unilateral ECT does seem to produce less confusion, memory loss and headache and appears to be equally effective in many patients[34,52]. However, there is a great deal of discrepancy in the results of comparative studies, possibly due to differences in diagnosis, age and gender, together with variance in the technique of administration of unilateral ECT. The consensus seems to indicate that, for many patients, both treatments are equally effective; some patients require more right unilateral treatments than bilateral to achieve the same result and some patients who do not respond to right unilateral ECT will respond when switched to bilateral treatment. Male gender and older age are also associated with better response to bilateral treatment.

It is my practice to use bilateral treatment initially in very severe psychotic depressives but right unilateral treatment in most other cases, particularly if there is evidence of prior cognitive impairment, switching to bilateral treatment if there is no response after six to eight right unilateral treatments. Brief pulse ECT at a moderately supra-threshold stimulus (which is often only around 275–350 millicoulombs) appears to offer efficacy, with the advantage of much less memory loss and confusion than the modified sine wave stimulus, and should be used in all cases, with a record of dosage received by the patient to ensure adequate technique[53].

There is considerable debate about the necessity to use a dose-titration technique to establish seizure threshold prior to treatment, with some viewing this as unnecessary and even detrimental in those patients requiring several non-convulsive stimuli. Adequate seizure response can be measured using inter-ictal EEG monitoring. Some clinicians seem to have developed an over-weaning

interest in stimulus intensity, seizure threshold and seizure duration. It is clear that seizure threshold will increase by about 40% during the course of ECT and the seizure duration will tend to decrease by about one-third. However, while it seems that outcome is not correlated with either seizure duration or threshold for bilateral ECT[35], it may be more important to keep the stimulus intensity above seizure threshold in unilateral treatment[36]. Seizure duration is more difficult to evaluate, as some patients regularly have brisk and brief responses with good results. The use of propofol to induce anaesthesia consistently reduces seizure duration, although apparently without affecting efficacy[37,38]. The use of caffeine prior to treatment to prolong seizure activity has been associated with improved efficacy in some patients[39]. It would seem that, as a rule of thumb, we should aim for a seizure length of around 25 s and any seizure less than 15 s or more than 120 s is likely to adversely affect response[40]. Cumulative seizure duration again seems less interesting now than it once was as a measure of the length of a course of treatment, and clinical response still seems the best measure.

There is no evidence that routine atropine premedication improves cardiac stability or lessens secretions. Theoretically it could cause confusion, but there is no convincing evidence of this either. Glycopyrrolate, which does not cross the blood–brain barrier, may be a better drug to use as a drying agent. Methohexitone for the induction of anaesthesia at a dosage of 30–50 mg is adequate to ensure sleep without hangover, and muscle relaxation with a suxamethonium dosage of 20–40 mg is enough to modify the convulsion without abolishing all evidence of motor activity. If the minimum amount of anaesthetic is combined with treatment early in the morning, the patient is not required to starve any longer than usual, he/she is less likely to be dehydrated, is less likely to break his/her fast, has less time to become anxious and agitated and will recovery quickly enough to enjoy a breakfast with the other patients on the ward. If this routine is combined with regular supervision of treatment by the prescribing psychiatrist, the patient will derive the maximum benefit from each treatment and the course will not be unnecessarily prolonged or ineffective. Outpatient ECT does not appear to be as effective in the elderly, except occasionally as maintenance, and consequently most patients will require admission to a specialist unit, where the effects of ECT combined with the therapeutic milieu will hasten improvement. Familiar staff administering the treatment and a well-designed ECT suite will help reduce anxiety.

MAINTENANCE AND CONTINUATION ECT

In 1990 the American Psychiatric Association task force on ECT defined continued administration of ECT over a 6 month period to prevent relapse after induction of remission as continuation ECT (C-ECT); treatment beyond 6 months was termed maintenance ECT (M-ECT). This was felt to be a viable form of management for selected patients.

Maintenance ECT has been used for many years: a survey of British psychogeriatricians in 1991[47] found that 20% were using it but there is little more than anecdote to support its use in the literature. Such studies as there are consist mainly of case-studies and small series of hospitalized patients, all of a ‘‘naturalistic’’ nature.

In a 1 year follow-up of nine elderly patients, continuation treatment, even if discontinued fairly quickly seemed to confer some lasting advantage in prevention of relapse[48], as did Petrides *et al.*'s study, looking at 33 courses of C-ECT[49]. The conclusion seemed to be that where patients have responded to acute ECT but previously failed on continuation pharmacotherapy there was compelling evidence for C-ECT and little therapeutic alternative. The four patients in this study[49] who continued with M-ECT remained well and the five who had previously stopped did not. Naturally this result is open to other interpretations, but it does suggest that C-ECT should be considered for those with recurrent depression who respond well to ECT acutely but receive no prophylaxis from pharmacotherapy. The practicalities of using outpatient M-ECT have prevented my using it more. Bringing elderly patients to hospital for outpatient ECT early in the day, from a rural catchment area some distance from the hospital, can be problematic, they soon lose enthusiasm for the treatment and consequently often withdraw consent. This is an issue recently addressed by Kim[50]. However, Schwarz's findings, that rehospitalization rates were reduced by 67% after instituting M-ECT, suggest that we should try and overcome the practical difficulties[51].

CONSENT

Popular myths about ECT are always more readily believed than the reality and can be part of what the patient believes they are consenting to. Occasionally patients consent as part of their death wish. I use a video of myself administering ECT to a patient seen before and after treatment, to show anxious or interested relatives and patients; no-one having seen it has then declined the treatment. There is one study suggesting that understanding is not enhanced by this method. The issue of informed consent in depressed patients is complex. As I have suggested, many care little and are prepared to do anything their doctor suggests, and patients' recollection of what was explained to them, after the ECT and when the depression has lifted, is often vague. A careful explanation should be made and recorded, and if there are doubts on either side a chance to preview the ECT room or an explanatory video may be helpful. However, it is doubtful whether the explanation of ECT is any less detailed than that of most surgical procedures and most people are willing to consent without seeing a video of the operation in question. Passive acceptance of ECT is often the case in the severely depressed but this should not prevent a full explanation, including consulting relatives if appropriate.

Involuntary ECT should never be given except within the guidelines of the relevant Mental Health legislation if we are to ensure the availability of ECT as a treatment option in the future. Nevertheless, depression is such a serious and debilitating illness that the chance of a cure through use of ECT should never be denied to a patient whose prognosis is favourable, simply through difficulty in obtaining actual written consent.

SIDE EFFECTS

As already mentioned, confusion and memory loss are often regarded as an inevitable corollary of ECT in the elderly, but this is clearly not the case and there are well conducted studies showing no objective permanent effects on memory, and in fact this often improves as a result of improvement in the depression[21,41,42]. Nevertheless, there is no doubt that some patients who were given bilateral sine wave ECT experienced long-term, even permanent, memory loss, and bland reassurances that this or even brief pulse bilateral ECT will not cause any memory loss is foolish and counterproductive. Some patients given bilateral brief pulse ECT may have amnestic gaps, but can be assured that no lasting effect on memory function, i.e. new learning or intelligence, will occur. The situation with right unilateral brief pulse ECT is different, with any subjective memory impairment being transient and undetectable 6 months later[43,44]. Patients with existing dementia may well show signs of memory impairment, even

with unilateral ECT. This may be acceptable in view of the relief from distress and agitation and improvement in behaviour and performance.

The cognitive side effects can be minimized by reducing concomitant medications, particularly benzodiazepines, anticholinergic antidepressants and lithium[45], although a recent study found no problems with the administration of ECT and lithium[46]. Benzodiazepines, given intravenously as the seizure ends, can be of use in controlling emergence delirium, which can last for 15–30 min after treatment and be very difficult to control otherwise[13]. Dementia *per se* does not preclude the use of ECT, provided that the coexisting depression is circumscribed. A history of depression before the dementia adds weight to the decision, particularly if there was a good response to ECT previously. Other side effects of treatment, such as headache and dizziness or muscle pain, usually only after the first anaesthetic, are minimal and soon forgotten as the depression lifts.

ECT is a valuable and as yet essential tool in the treatment of depression in old age, a disease which untreated carries a significant mortality. It is interesting that in my practice elderly patients who have attempted suicide are nearly all offered ECT. This is because those, albeit only very few in number, who have subsequently killed themselves during a depressive illness have all been patients who have either refused ECT or not been given it at the time of their index suicide attempt. However, whilst there are many compelling arguments for the use of ECT, it is not a universal panacea. ECT, like any potent treatment, should be prescribed with accuracy and its use monitored carefully by those prescribing it.

Depression in the elderly presents with protean manifestations. ECT should be part of an eclectic approach to treatment and as such will continue to relieve distress and save lives.

Pharmacological Treatment of Depression

Mohammed T. Abou-Saleh
St George's Hospital Medical School, London, UK

A recent review[1] identified mood disorders as a major public health problem, with poor recognition, diagnosis and treatment despite the availability of reasonably safe, effective, economical treatments and the established effectiveness of continuing educational programmes for care providers. The magnitude of the following problems is greater in the elderly with mood disorders: poor recognition for most somatic and cognitive symptoms; increased physical morbidity and disability; and high mortality from suicide and other causes. This situation, however, is balanced by the availability of effective pharmacological treatments, which are successful in two-thirds of patients within few weeks of treatment, who remain well 1 year later. However, the temporal profiles of the course of late-life depression during treatment shows marked variation in rate, stability and direction of recovery with reliable pretreatment predictors of outcome[2]. The usefulness of pharmacological treatment for patients with subsyndromal depression has not, however, been investigated[3].

PRETREATMENT CONSIDERATIONS

There are a number of pretreatment considerations before starting specific pharmacological treatment of mood disorders in the elderly[4,5]. With advancing age, there are important and clinically significant changes in distribution, metabolism and elimination of these drugs[6]. The age-related increase in volume of distribution results in a longer half-life for all psychotropic drugs. Hepatic drug metabolism decreases with age, also resulting in a prolonged half-life, which may be two to three times longer than in younger patients, and the decrease in renal function with advancing age is particularly relevant with regard to lithium, which also results in two to three times higher plasma levels than those in younger patients on the same daily dose. Of particular importance, however, has been the study of the inhibitory effects of the selective serotonin reuptake inhibitors (SSRIs) on the cytochrome p450 enzymes; these pharmacodynamic actions have pharmacokinetic consequences for co-administered drugs, such as tricyclic antidepressants (TCAs), which are dependent on these enzymes for biotransformation.

To determine the best pharmacological treatment options for individual patients requires careful consideration of a number of clinical factors, which include the following: type of mood disorder; degree of urgency for treatment; previous response to treatment; concurrent medical problems; concurrent drug therapy; risk of overdose; reasonable half-life; dosing flexibility, and affordability[7].

TREATMENT OF DEPRESSION

Elderly patients with depression could be successfully treated with conventional TCAs, monoamine oxidase inhibitors (MAOIs), SSRIs and atypical antidepressants. A recent update of the evidence reported the results of 26 RCTs of pharmacological treatments and 21 of these were placebo-controlled. People were recruited mainly from outpatient clinics. Significant benefits were found for fluoxetine, trazodone and phenelzine. Of the 17 drug vs. drug comparisons (mainly involving heterocyclic drugs), none showed significant benefit above the others. In people with depression plus a physical illness vs. placebo, one systematic review of 18 RCTs found that antidepressants were more effective than placebo in people with depression and a physical illness. TCAs have the major limitations of anticholinergic effects, postural hypotension, excessive daytime sedation and cardiotoxicity in overdose. Their advantages, however, are their established efficacy and low cost. A number of recent reviews[4,6,7] identified the secondary amines desipramine and nortriptyline among the TCAs having more favourable side-effect profiles, with desipramine having the fewest anticholinergic effects and nortriptyline causing the least postural hypotension. The secondary amines also have the advantage of therapeutic drug monitoring, with an established therapeutic window for nortriptyline and a therapeutic plasma level of desipramine. Therapeutic drug monitoring enables the clinician to determine the minimal therapeutic dose and to monitor compliance. Nortriptyline has been well investigated for use in elderly patients, including patients older than 80 years[8] and patients who have had strokes[9].

Among the MAOIs, phenelzine has been shown to be effective in treating elderly patients with depression[10,11], particularly for patients who could not tolerate TCAs and those with resistant depression. Their main limitation is their interaction with tyramine-rich foods, causing hypertensive crisis. For this, they are superseded by moclobemide, a reversible and selective inhibitor of monoamine oxidase type A. Comparative trials in the elderly have established its efficacy compared with imipramine[12], nortriptyline[13] and placebo[14]. Moclobemide also showed enhancing effects on cognition in patients who had dementia and depressive symptoms[14].

The SSRIs, however, have provided a major advance in the successful and safe management of depression in late life. These include fluoxetine, fluvoxamine, sertraline, paroxetine and citalopram. The advantages of SSRIs over TCAs are the absence of anticholinergic effects, orthostatic hypotension and arrhythmia in the side-effect profiles, and their safety in overdose[7]. The consensus statement update from the US National Institutes of Health[3] on the diagnosis and treatment of depression in late life concluded that the SSRIs are roughly equivalent to TCAs in

efficacy in the elderly, with 60–80% of patients responding to treatment. The authors concluded that the efficacy data are not robust when an SSRI is compared with placebo; the only available report from a randomized placebo-controlled trial of fluoxetine in outpatients[15] found a lower drug–placebo difference than that found for many studies with TCAs. Moreover, comparison of fluoxetine with nortriptyline in inpatients with severe depression and heart disease showed that nortriptyline may be more effective in this population[16]. A meta-analysis of the comparative efficacy and safety of SSRIs and TCAs in elderly patients[17] showed no differences in safety and dropout rates.

The side-effects profile of SSRIs includes nausea, diarrhoea, insomnia, headaches, agitation, anxiety and sexual dysfunction. The SSRIs also seem to worsen parkinsonism. As with other antidepressants[18] there have been case reports of hyponatraemia, hypomania and seizures[7]. An important aspect of their use is their drug–drug interactions, and their inhibitory effects on hepatic cytochrome p450 isoenzymes, the route through which many drugs commonly prescribed for elderly people are metabolized[19]. Paroxetine, norfluoxetine and sertraline have clinically important inhibitory effects (*in vivo*) on cytochrome P2D6, resulting in increased plasma concentrations of co-administered TCAs, such as desipramine, and antipsychotics, such as haloperidol[20]. Sertraline, however, had a modest effect on plasma nortriptyline levels in depressed elderly patients[21]. Fluoxetine increases plasma levels of co-administered carbamazepine; alprazolam and fluvoxamine increase plasma concentration of co-administered TCAs and antipsychotics by inhibiting cytochrome P1A2[9]. An extensive list of drugs metabolized by various p450 isoenzyme types is provided in the reviews by Catterson *et al.*[5] and Rivard[7].

CONTINUATION AND PROPHYLACTIC TREATMENT

Early studies indicated a poor outcome of late-life depression[25], with high relapse, recurrence and chronicity. This view was based on naturalistic observation without monitoring of compliance, adequate dosage and duration of treatment, including prophylactic treatment, and was therefore challenged[26]. Controlled studies of maintenance antidepressant medication, however, showed better outcome for late-life depression[27]. The Pittsburgh group reported a 3 year follow-up study of maintenance treatment with nortriptyline or placebo with or without interpersonal psychotherapy (IPT)[28] and showed that 80% of patients assigned to nortriptyline, with or without IPT, remained in remission. The Pittsburgh group also identified the elderly patients who remained well after placebo-controlled discontinuation of antidepressant medication for a period of 1 year. Recovery of good subjective sleep quality by early continuation treatment was useful in identifying which remitted elderly depressed patients remained well with monthly IPT after discontinuation of antidepressant medication[29]. Moreover, effective maintenance treatment with nortriptyline was associated with enhancement in the rate of delta-wave production in the first non-rapid eye movement sleep and of rapid movement activity throughout the night[30].

A recent study of the effect of treatment on the 2 year course of late-life depression[31] showed a 74% survival rate without relapse. This good outcome was obtained by the use of full-dose antidepressant medication, frequent follow-up and rigorous treatment of relapse.

The US National Institute of Mental Health consensus statement update[3] concluded that recent evidence supports the recommendation for at least 6 months of treatment beyond recovery for those with first onset in late life, and for at least 12 months for those with a recurrent illness[32]. Moreover, prophylactic treatment should be of the same type and of same dosage as that which was successful in the initial acute phase. The consensus statement also concluded that treatment response and long-term outcome for all the patients is generally similar to that observed in younger adults, but the temporal course may be somewhat slower in the elderly and risk of relapse somewhat greater[3]. The use of lithium in continuation and prophylactic treatment of depression in the elderly has also been recommended[27,33,34], with the use of lower doses/plasma levels[34]. Lithium may be a more favourable prophylactic treatment than antidepressants in recurrent depression with melancholia and in depression with psychotic features (delusional depression), which are particularly common among the elderly, with a tendency to respond less well to antidepressants[26,34]. The other advantage of lithium therapy is the evident decreased mortality, whether from suicide or other causes[35]. A recent 1 year prospective, placebo-controlled study of maintenance lithium in conjunction with cognitive–behavioural psychotherapy in elderly depressed patients[36] showed that, although cognitive–behavioural psychotherapy reduced depression severity during follow-up, lithium therapy was no better than placebo. This appears to be related to poor compliance, a finding that highlights the serious difficulties in undertaking prophylactic studies in elderly depressed patients.

TREATMENT OF BIPOLAR DISORDER

Elderly patients with late presentation or late-onset mania respond well to standard antimanic treatment with neuroleptics, lithium and anticonvulsants[37]. Neuroleptic treatment is best avoided in the elderly because of its known extrapyramidal side effects, except for floridly psychotic, agitated and behaviourally disturbed patients who need rapid control of symptoms. Lithium remains the treatment of choice, followed by valproic acid[37]. The evidence for the efficacy of lithium in late-life mania is based on retrospective and uncontrolled studies; there have been no controlled studies, and there have been no controlled studies of the efficacy of anticonvulsants in late-life mania. It has been suggested that valproate is a safer alternative treatment to lithium than carbamazepine, whether used as single or adjunct treatment, in elderly manic patients[37]. There are no guidelines regarding the optimal plasma concentration of valproate in relation to efficacy[37].

A recent evidence-based review of the treatment of mania, mixed state and rapid cycling in younger populations[38] concluded that lithium and divalproex sodium are effective in mania, whereas divalproex sodium and carbamazepine are more effective in mixed states. Divalproex sodium is the drug of choice for rapid cycling disorder. With bipolar depression, lithium is recommended as a first-line treatment and the addition of a second mood stabilizer or the TCA would be an appropriate next step[39].

The guidelines for the continuation and prophylactic treatment of bipolar illness in late life are similar to those advocated for younger patients, except for the notion of high recurrence rates necessitating prophylactic treatment, even after a first-onset manic episode. Lithium remains the medication of choice for prophylaxis[34]. An open naturalistic study of lower doses/plasma-lithium levels of lithium[34] showed efficacy in the elderly comparable to that in younger patients at plasma lithium levels as low as 0.4 mmol/l, with fewer side effects and renal and thyroid adverse effects.

TREATMENT-RESISTANT DEPRESSION

Treatment-resistant depression occurs in one-third of elderly depressed patients[40] and can only be ascertained after adequate recognition, compliance with treatment and effective treatment[41].

It has also been related to cognitive impairment, physical and psychiatric co-morbidity, late onset and presence of melancholic and psychotic features[41]. Moreover, elderly patients with anxious depression are less responsive to nortriptyline than are those without significant anxiety symptoms[42].

Although TCAs[16] and MAOIs[43] have shown efficacy, the SSRIs are specifically advocated[41]. Fluvoxamine has shown efficacy (70% good response) in desipramine non-responders[44,45], and patients who were intolerant of fluoxetine completed a trial of sertraline with a response rate of 76%[46]. Efficacy has also been shown for trazodone[47], bupropion[48] and venlafaxine[49]. Combination and augmentation strategies have been advocated[41]. Lithium augmentation in TCA non-responders is effective in 20–65% of cases[50–52]. It is, however, conducive to cognitive and neurological side effects in 50% of patients[50,51,53,54]. Lithium has been successfully added to SSRIs, notwithstanding the risk of neurotoxicity with an SSRI–lithium combination[41]. Advocated augmentation/combination strategies includes TCA/triodo-thyronine; SSRI/TCA; SSRI/anticonvulsants; and SSRI/oestrogen[41], and elderly patients requiring adjunctive medication to achieve remission may need continuation of adjunctive medication to remain well and to avoid early relapse[55].

For refractory bipolar disorders, a recent review[56] concluded that the safest combination of mood stabilizers is valproate plus lithium. This was also shown in a series of elderly patients with lithium-resistant rapid cycling mania[57].

CONCLUSION

Although there have been impressive advances in the pharmacological treatment of mood disorders in general, there has been a relative paucity of controlled studies in the elderly, particularly in maintenance and prophylaxis. Generalization from the results of studies of younger patients may be inappropriate in view of the significant changes associated with normal ageing and concomitant medical illness, which affect the pharmacokinetics and pharmacodynamics of psychotropic drugs.

Nevertheless, there has been a change of culture. The nihilism that had prevailed in the treatment of mood disorders in late life has been replaced by cautious optimism with regard to the results of controlled trials in naturalistic settings, as well as studies in high-risk groups, including patients with multiple medical conditions and subsyndromal states.

A large majority of elderly patients with depression could be treated successfully with antidepressants, particularly the SSRIs, because of their favourable side-effect profiles and their low toxicity in overdose. The SSRIs, however, challenge the clinician with their clinically significant drug–drug interactions. Patients who improve should receive continuation of prophylactic treatment with the same dose. For mania, lithium remains the optimal treatment, with anticonvulsants, particularly divaloproex, providing a second-line treatment. The efficacy and safety of atypical neuroleptics remain to be evaluated in both acute and long-term management of bipolar illness. There is also hope for those with resistant-mood disorders with the design of augmentation/combination strategies, which require further evaluation.

Treatment-resistant Depression

Alastair J. Flint

Toronto General Hospital, Toronto, Ontario, Canada

Treatment resistance is a common clinical problem, reported in up to one-third of older depressed patients[1]. Many patients labelled as "treatment-resistant" in fact have not had an adequate course of treatment[2]. Therefore, the first step in achieving remission of depressive symptoms is to ensure that the patient has been given, and has complied with, an optimum dose of antidepressant for a sufficient length of time (at least 6 weeks). In treatment-resistant depression, it is also important to investigate the patient for unidentified physical conditions (such as hypothyroidism, vitamin B_{12} or folate deficiency, or hypercalcemia) that could be contributing to poor antidepressant response[2].

In patients who have failed to respond to an adequate trial of antidepressant medication, the following options can be considered: (a) augment the antidepressant with another drug that is not primarily an antidepressant, such as lithium, triiodothyronine, methylphenidate, pindolol, buspirone or valproate; (b) add a second antidepressant to the first (combination therapy), e.g. add a tricyclic antidepressant (TCA) or bupropion to a selective serotonin-reuptake inhibitor (SSRI); (c) switch to a different antidepressant medication; or (d) switch to electroconvulsive therapy (ECT). The advantage of augmentation or combination therapy is that they do not require discontinuation of the original antidepressant and, therefore, patients who have partially responded to treatment are not put at risk of returning to their baseline severity of depression. Also, response may at times be faster with augmentation/combination than with a new trial of antidepressant medication. The disadvantage of these strategies, especially in older people, is that the combination of medications increases the risk of side effects and drug–drug interactions. Also, there have been no placebo-controlled trials of augmentation or combination therapy in elderly depressed patients and so their efficacy has not yet been established in this population[2,3].

There are virtually no research data on switching from one antidepressant medication to another in refractory geriatric

Treatment-resistant Depression

Alastair J. Flint
Toronto General Hospital, Toronto, Ontario, Canada

Treatment resistance is a common clinical problem, reported in up to one-third of older depressed patients[1]. Many patients labelled as "treatment-resistant" in fact have not had an adequate course of treatment[2]. Therefore, the first step in achieving remission of depressive symptoms is to ensure that the patient has been given, and has complied with, an optimum dose of antidepressant for a sufficient length of time (at least 6 weeks). In treatment-resistant depression, it is also important to investigate the patient for unidentified physical conditions (such as hypothyroidism, vitamin B_{12} or folate deficiency, or hypercalcemia) that could be contributing to poor antidepressant response[2].

In patients who have failed to respond to an adequate trial of antidepressant medication, the following options can be considered: (a) augment the antidepressant with another drug that is not primarily an antidepressant, such as lithium, triiodothyronine, methylphenidate, pindolol, buspirone or valproate; (b) add a second antidepressant to the first (combination therapy), e.g. add a tricyclic antidepressant (TCA) or bupropion to a selective serotonin-reuptake inhibitor (SSRI); (c) switch to a different antidepressant medication; or (d) switch to electroconvulsive therapy (ECT). The advantage of augmentation or combination therapy is that they do not require discontinuation of the original antidepressant and, therefore, patients who have partially responded to treatment are not put at risk of returning to their baseline severity of depression. Also, response may at times be faster with augmentation/combination than with a new trial of antidepressant medication. The disadvantage of these strategies, especially in older people, is that the combination of medications increases the risk of side effects and drug–drug interactions. Also, there have been no placebo-controlled trials of augmentation or combination therapy in elderly depressed patients and so their efficacy has not yet been established in this population[2,3].

There are virtually no research data on switching from one antidepressant medication to another in refractory geriatric

depression. Flint and Rifat[4] found that seven of 15 elderly patients (47%) who had failed to respond to 6 weeks of nortriptyline followed by 2 weeks of lithium augmentation subsequently responded to a 6 week trial of phenelzine. This rate of response is comparable to that reported among younger patients refractory to TCAs[5]. Data obtained from mixed-aged patients with resistant depression suggest that switching to an antidepressant within the same class is less effective than switching to one from another class[5]. If a patient has failed to respond to an SSRI or nefazodone, then switching to an antidepressant with dual neurotransmitter action (e.g. venlafaxine, mirtazapine or nortriptyline) is a reasonable approach.

Although substitution of treatment usually involves switching from one antidepressant medication to another, switching from an antidepressant to ECT should also be considered. The efficacy of ECT in patients who have failed to respond to adequate antidepressant pharmacotherapy is lower than in patients without established medication resistance[6]. Nevertheless, no antidepressant, alone or in combination, has been shown to be more effective than ECT in treatment-resistant depression and ECT remains a valuable option in this situation.

Psychotherapy of Depression and Dysthymia

Thomas R. Lynch[1] and Christine M. Vitt[2]

[1]*Duke University Medical Center and* [2]*Duke University, Durham, NC, USA*

BACKGROUND

Depression in the elderly is a treatable disorder. Although antidepressant medication has traditionally been considered a first-line intervention, psychotherapy has been shown to be *at least* equally effective[1–3]. The NIH Consensus Development Conference on Diagnosis and Treatment of Depression in Late Life concluded that psychotherapy was an important treatment option for elderly depression, although not sufficient by itself[4–6]. This conclusion has been challenged in the literature, with reviews of psychotherapy research finding a powerful effect of psychotherapy alone on depression as compared to wait-list controls[1,3,7]. Additional research on the combination of medication and psychotherapy for elderly depression has shown promising results for both acute treatment and relapse prevention[8]. Less is known about the treatment of dysthymic disorder, although its similarities to major depressive disorder suggest that aggressive treatment is the most powerful treatment option.

This chapter reviews the theoretical elements and empirical evidence supporting the use of psychotherapy to treat elderly depression. First, we examine special issues associated with treating elderly depression using psychotherapy. Next, we review the theoretical foundations and evidence for the use of psychotherapy with older adults, including cognitive-behavioral, psychodynamic, interpersonal and group interventions. Finally, we examine recent theoretical developments and research that have addressed problems associated with relapse prevention, treatment-resistant depression, and co-morbid personality disorders.

SPECIAL ISSUES IN PSYCHOTHERAPY WITH OLDER PATIENTS

Psychotherapy is a particularly useful option for depressed patients who cannot or will not tolerate medication, or who are dealing with stressful conditions, interpersonal difficulties, limited levels of social support and/or recurrent episodes of depression[6,8,9]. Although it has been established that psychotherapy and medication are effective treatments for major depression, there is a sizeable literature highlighting the underdiagnosis and undertreatment of late-life depression[10–16]. Consequently, millions of older persons deserving of mental health care go untreated[17]. Friedhoff[14] indicated that only 10% of older adults in need of psychiatric services actually receive professional care and there has been minimal utilization of mental health services in this age group[16,18,19].

Under Diagnosis

Older adults are more likely to see general practitioners than mental health professionals, essentially leaving the responsibility for diagnosis of late-life depression in primary care. Although physicians are more likely than mental health professionals to see depressed older adults, this does not mean that elderly patients will purposefully present with depressive symptoms. Studies have shown that up to 75% of older adults who complete suicide had seen their physician in the previous month, emphasizing the important role general practitioners play in diagnosing clinical depression[20]. In a non-depressed community sample of 462 older adults, 40% indicated they would keep depressive symptoms to themselves and not report them to anyone[21]. Of those who would seek help, over half (52%) indicated they would talk to their regular doctor. Allen *et al.*[22] surveyed attitudes toward treatments for depression in older and younger inpatients. The older group, particularly those identified as depressed, was less likely to approach anyone for help. In addition, the older adults had more negative attitudes about approaching their physician than the younger group.

Hesitation to seek help for mental health problems should not be considered unfounded. Link and colleagues[23] have identified a social stigma associated with undergoing treatment for psychiatric dysfunction. However, treatment outcome research suggests that gains in well-being likely outweigh any stigma associated with the disorder. Hence, coming to an understanding of the origins of these attitudes may assist in developing educational interventions addressing the needs of this age group.

This descriptive research highlights several issues of concern for the diagnosis of depression. First, general practitioners typically bear the responsibility for the diagnosis of depression in their older patients, despite the possibility that patients may not feel comfortable about discussing depressive symptoms with others. Making this more difficult have been reports that older patients may not recognize that they have symptoms, or may pass off symptoms as signs of other physical conditions[10]. Second, not all older patients regularly see general practitioners. For these older adults, informal resources (family, friends, religious sources) are left with the responsibility of identifying changes in moods and the need for professional intervention. Third, psychiatrists and

psychologists have greater expertise for accurate diagnosis, yet typically only encounter a potential patient after referral from a general practitioner. In addition, mental health professionals specializing in work with geriatric populations are still in the minority and most training programs for both psychology and medicine do not emphasize geriatric mental heath issues. This only exacerbates the factors that make recognition less likely to occur[24,25]. In order for improvements in detection to occur, all three areas discussed above will need to be addressed. Physicians will need to enhance their ability to detect depressive symptoms and make quick treatment decisions during increasingly short office visits. Relatives and other informal sources of referral will require greater education regarding depressive symptoms and encouragement to report those symptoms. Finally, a greater number of mental health professionals will need to obtain specific training in geriatric issues and increase their visibility among potential referral sources.

Under Treatment

Ideally, if the dilemma of underdiagnosis of late-life depression could be resolved, under treatment would not be a problem. However, this does not appear to be the case. Research indicates that even cases that are diagnosed are not necessarily treated. Koenig *et al.*[13] reported that 34% of hospitalized medically ill elderly patients with a diagnosis of depression in their charts were not treated with antidepressant medication during their inpatient stay or during a 45 week follow-up period, neither were these patients referred to psychotherapy. Only 12.4% of the sample had documented psychotherapeutic intervention in their medical charts at discharge[13]. Thus, not only does recognition appear to be a difficulty, but under-treatment as well. The question is why?

Many practitioners assume that older adults have negative attitudes toward psychotherapy as a treatment for depression. However, research on attitudes toward treatment in elderly samples is not conclusive, with considerable descriptive research suggesting that older adults may prefer counseling over medication treatment for depression. Sixty-eight percent of the previously mentioned non-depressed community-dwelling older adult sample agreed with a statement that professional counseling or therapy helps most depressed people feel better. Interestingly, 56% of the same sample reported that they believed antidepressant medications to be addictive, and only 4% disagreed[21]. Older adults have also been shown to report a greater number of positive attitudes toward mental health professionals, and to be less concerned with stigma attached to seeking treatment for depression relative to younger adults[26]. On the other hand, Allen *et al.*[22] found attitudinal barriers to treatment in a survey of both younger adult and older adult inpatient samples. However, in the older sample, the pattern of preference for counseling and psychotherapy over medication persisted, with 95% of the older group agreeing that "people with depression should be offered counseling", and 46% agreeing that "people with depression should be treated with antidepressant tablets"[22]. Hence, it appears that interventions addressing these issues must educate practitioners to evaluate their assumptions about elderly preferences for treatment, as well as educate older and younger adults about available treatment options.

PSYCHODYNAMIC THERAPY

This type of treatment is based on psychoanalytic theory that views current interpersonal and emotional experience as influenced by early childhood experience. This experience results in the development of a complex inner world shaped by both unconscious and conscious mental processes. There have been a variety of theoretical formulations developed over the years that have utilized a psychodynamic formulation to treat depression, including classic psychoanalytic theory[27], ego-psychology[28], self-psychology[29] and object-relations theory[30]. Revised conceptualizations have emphasized understanding how relationships are internalized and transformed into a sense of self[29–32]. Because early interactions with caregivers are so tied up with emotional gratification and deprivation, the interaction with mother is viewed as a template for all subsequent relationships. Psychopathology is theorized as related to arrests in the development of the self and depression is viewed as a symptom state resulting from unresolved intrapsychic conflict, which may be activated by life events such as loss.

There have been several indications in the geriatric depression literature that short-term psychodynamic therapy, particularly as conducted by Thompson, Gallagher-Thompson and colleagues[33,34], is an effective means to treat depression in older samples. In studies with random assignment to wait-list control, short-term psychodynamic therapy or cognitive-behavioral therapy, there were no significant differences between the types of psychotherapy at the end of treatment or at 12 and 24 month follow-ups. Additional research on depressed caregivers demonstrated an interaction between mode of therapy and length of caregiving, such that those who had been providing care for less than 44 months appeared to improve more from dynamic therapy, whereas longer-term caregivers seemed to benefit most from CBT[35]. The authors suggested that the long-term caregivers needed the skills learned in CBT in order to care for family members with more pronounced deficits and requiring more complicated care. These interesting results call for additional controlled trials comparing different treatment modalities, continued component analysis research, and continued research that examines which type of treatment works best with which type of patient.

LIFE REVIEW AND REMINISCENCE THERAPY

Life review and reminiscence therapies are psychoanalytically orientated approaches to psychotherapy for depression. Life review therapy includes a review of life experiences in order to revisit and resolve old conflicts and reintegrate life experiences[36,37]. Conflicts emerge in interviews about past life experiences, in both acknowledgment and omission. Reminiscence therapy differs from life review in that the focus is on enhancing self-esteem and social intimacy by recounting past experiences, rather than directly resolving past conflicts[2,38]. Lewis and Butler[37] suggest several techniques to encourage elderly clients to participate in the life review process. Written and taped autobiographies, pilgrimages to the place of childhood, reunions, scrapbooks and photographs are tools that can stimulate past memories. A crucial component of any life review therapy is careful, attentive listening on the part of the therapist[36,38].

Results on empirical research of life review and reminiscence therapies are promising, but inconsistent. Teri and McCurry[2] reviewed 12 empirical studies using reminiscence techniques. Results were mixed, likely due to the range of patient populations (institutionalized, homebound, community-dwelling), treatment duration (1–10 sessions), type of therapy (group, individual) and diagnosis (major depression, no diagnosed psychopathology). Also, the distinction between life review and reminiscence therapy has not been clearly operationally defined, resulting in an ambiguous designation of the differences between the two therapies.

Research does suggest that the amount of structure in reminiscence therapy may influence outcome[39]. Fry[39] compared individual structured reminiscence therapy, non-structured reminiscence and non-reminiscence visits in a sample of moderately depressed elderly. Subjects in the non-reminiscence control group had significantly higher post-treatment depression scores than those in either reminiscence group; the subjects in the structured reminiscence groups had lower depression scores than those in the unstructured reminiscence groups. Reminiscence group therapy has also been tested in nursing home residents with dementia and has been found to reduce self-reported symptoms of depression to a greater degree than subjects in supportive therapy or control groups[40]. However, the therapy did not improve cognitive or behavioral outcomes, and the reduction in depression was short-lived[40]. Rattenbury and Stones[41] found that both reminiscence and current event discussion groups showed positive changes on measures of psychological well-being when compared to non-treatment controls. However, because subjects were not selected for high depression scores, this was not an empirical test of treatment for *clinical depression*. Yet the results do suggest that there is something beneficial about client-focused interaction, a fundamental component of any form of psychotherapy.

INTERPERSONAL PSYCHOTHERAPY

Interpersonal psychotherapy (IPT) is a manualized, time-limited outpatient treatment for depression, focusing on current interpersonal issues in four problem areas: interpersonal disputes, role transitions, interpersonal deficits and abnormal grief[42]. The therapist and client collaborate to identify which problem area to focus on in treatment; commonly, more than one problem area is chosen. Klerman *et al.*[42] pointed out that, regardless of the origin of depression (genetic, biochemical, developmental vulnerability, personality), the condition is expressed within an interpersonal context. The initial goal of therapy is to reduce symptoms of depression, but the over-arching goal is to improve the patient's social functioning and interpersonal relationships[43]. With its emphasis on addressing interpersonally relevant problems, IPT appears particularly well suited to the life changes that many older people experience. Techniques utilized in treatment include: role playing, communication analysis, clarification of the patient's wants and needs, and links between affect and environmental events[44]. Frank and colleagues[45] have developed separate treatment manuals for IPT in late life (IPT-LL) and interpersonal maintenance therapy for older patients (IPT-LLM) (cited in ref 44). These manuals include adaptations specific for use in elderly patients, including, but not limited to, flexibility in length of sessions, long-standing role disputes, and the need to help the patient with practical problems.

Controlled trials in adult depressed populations have demonstrated the efficacy of IPT for the treatment of acute depression (reviewed in refs 43, 44). IPT has also been found as effective in the acute treatment of major depressive disorder in elderly patients as nortriptyline[46]. Of additional importance were findings that elderly patients in IPT treatment were less likely to drop out of treatment than those taking nortriptyline, because of the medication's side effects.

Research from the Reynolds group at the University of Pittsburgh has shown IPT in combination with nortriptyline to be an effective treatment for elderly depression in geriatric samples[47,48]. In an attempt to understand more regarding the treatment of elderly patients with recurrent depression, Reynolds *et al.*[47] selected patients only if they reported at least one prior episode of depression. The authors reported that 78.4% (116/148) remitted during the acute phase of treatment (8–14 weeks). During the continuation phase, 15.5% (18/116) experienced relapse of major depression; thus, a total of 66.2% patients recovered fully[47,48]. Consequently, the authors concluded that older patients with recurrent major depression can successfully be treated with a combination of antidepressant medication and interpersonal psychotherapy, and that older patients respond as well, albeit more slowly, than middle-aged patients[49].

COGNITIVE-BEHAVIORAL THERAPY

The cognitive model of depression[50] is based on the notion that, as a consequence of early learning, depressed individuals develop stable cognitive schemas or core beliefs which predispose them to negative interpretations of life events (i.e. cognitive distortions). This distorted style of thinking is hypothesized to result in depressive behavior and experience.

Cognitive-behavioral interventions for depression typically involve three active components. First is a behavioral activation component, in which the patient is exhorted to increase activities that are reinforcing, and thus increase the amount of pleasurable experience in life. Second, automatic dysfunctional thoughts are identified, explored, challenged and replaced with more accurate cognition, based on a thorough assessment of the patient's contextual environment. Third, underlying cognitive schemas or structures, which are hypothesized to drive automatic cognitive distortions and limit access to experiences that may alter these schemas, are identified and altered to more accurately reflect the patient's actual environmental, social and personal experience. Recent component analysis research suggests that behavioral activation and automatic thought modification are equally effective, and both components together are no more effective in preventing relapse than when used alone[51,52].

More purely behavioral interventions are derived from classic learning theory, in which problem behaviors are viewed as the result of specific antecedent stimuli and consequential events that reinforce, punish or maintain behavioral responses[53]. This therapeutic approach views depression as a state in which there is a relative shift toward an increase in certain aversive affective reactions (respondent processes) and a concomitant reduction in the frequency of overt activities (operant extinction or punishment). In addition, histories of pervasive inescapable punishment, reinforcement of distressed behavior, classically conditioned dysphoric responses, and the evocative salience of certain stimuli depending on mood, may be examined as part of a functional analysis of depressed behavior[53,54]. For example, a previously active person suffering from a serious illness may experience a reduction in the frequency of self-esteem-generating activities and positive social contacts, as well as increased dependency on others for the provision of positive reinforcers, and may feel bored, helpless and pessimistic. Restoration of the predictability and availability of positive reinforcers, and reduction in negative reinforcers (i.e. avoidance behaviors), is seen as linked to the curative process, with goals of symptom reduction and increased skill at identifying and obtaining appropriate reinforcement. Techniques used might include monitoring behavior and affect patterns, assigning pleasant events, stimulus control, limiting worry and depressive ruminations with time limits, behavioral exposure, and skills training (relaxation, problem-solving, interpersonal skills).

A related therapy for elderly depression, which utilizes elements associated with both cognitive and behavioral interventions described above, examines problems associated with social problem solving. Social problem-solving therapy (PST) is based

on a model in which ineffective coping under stress is hypothesized to lead to a breakdown of problem-solving abilities and subsequent depression[55,56]. Therapeutic approaches involve identifying and modifying maladaptive beliefs or attitudes associated with ineffective problem-solving while increasing motivation to generate alternative solutions, make decisions, implement solutions and assess solution utility.

Outcome studies have supported the use of cognitive and behavioral psychotherapy in treatment of depression in elderly samples (*see* reviews[1,7,33,57]). In a study comparing cognitive, behavioral and brief psychodynamic therapy to wait-list controls, Thompson *et al.*[33] found that all of the treatment modalities led to comparable and clinically significant reductions of depression. All three treatment regimens included individual treatment twice weekly for 4 weeks and weekly thereafter, totaling 16–20 sessions. Overall, 52% of the sample attained complete remission after treatment, and 18% showed significant improvement, with some enduring depressive symptoms. These rates are comparable to treatment outcomes in younger adult populations and response to pharmacotherapy[33,58]. Follow-up research indicated that at 12 months after treatment 58% of the sample was depression-free, and at 24 months 70% of the sample was not depressed. As in acute treatment, there were no differences between treatment modalities at follow-up[34], although in previous research with a smaller sample size depressed geriatric patients in cognitive and behavioral therapies maintained the gains longer than those treated in brief psychodynamic therapy[59]. Arean *et al.*[60] examined the efficacy of PST in a randomized controlled trial of 74 clinically depressed older adults (age 55 and over). Patients were assigned to one of three treatment conditions: problem-solving therapy (PST); reminiscence therapy (RT); or a waiting-list control. Following 12 weekly sessions, both therapies showed significant reductions in depressive symptoms at post-treatment and at a 3 month follow-up, relative to controls. However, PST showed a significantly greater number of patients, compared to RT, who were classified as improved or in remission following treatment.

Subsequent research on the same sample used in the Thompson[33] study examined the role of change expectancies relative to outcome[61]. Of those who were assigned to cognitive therapy, subjects who originally indicated that they expected a change from cognitive and behavioral processes attained greater improvement. In addition, some elderly patients, more familiar with the "doctor takes care of patient" mentality pervasive in medicine, may not be accustomed to the hard work involved on the part of the patients for the success of cognitive-behavioral therapy. Thompson *et al.*[62] recommend addressing such views directly, while helping the patient to gain insight into how his/her thoughts influence mood and how new skills can help in coping with stressful events and automatic thoughts.

GROUP INTERVENTIONS

Group therapy has been shown efficacious for depression in adult samples[63] and in geriatric samples[64]. Non-specific treatment factors that may influence positive outcomes include diffusing dependence on individual therapists, as well as providing a supportive social network. In addition, with the relative dearth of coverage for mental health care among many insurance providers, and the relative lack of parity for mental health care in Medicare, the lower cost of group therapy may be a more appealing option in older patient populations.

Beutler and colleagues[64] tested the relative and combined effectiveness of alprazolam and group cognitive therapy in a sample of 56 depressed older adults. Subjects were assigned to one of four groups: alprazolam and weekly management sessions; placebo and weekly management sessions; cognitive therapy plus alprazolam; and management and cognitive therapy plus placebo. The cognitive therapy groups were held in 12 weekly 90 min sessions. Patients in group therapy showed a significant and consistent decline in BDI scores, while those not in group therapy failed to produce significant changes. Also, a significantly higher proportion of those in group cognitive therapy were asymptomatic at the end of follow-up (29% vs. 12%). Although the results indicate that the cognitive therapy group was more effective in reducing depressive symptoms than alprazolam, this drug (a type of benzodiazepine) is not a recommended medication for depression. However, it appears that benzodiazepines remain a relatively commonly prescribed medication in medical practice. In a sample of depressed inpatients at a large university medical center during 1993–1996, 25% of patients diagnosed with depression by a geriatric psychiatrist were prescribed only benzodiazepines by their physicians[13]. Koenig *et al.*[13] also found that newer and older antidepressants were prescribed with the same frequency, suggesting that the prescribing practices of many physicians do not include the newer, safer antidepressants. Despite the fact that benzodiazepines are still used in clinical practice for depression, a revised research project using one of the newer antidepressants in Beutler's design would be informative for today's clinicians.

Steuer *et al.*[65] investigated cognitive-behavioral therapy (CBT) and psychodynamic group therapy in a sample of 33 depressed elders. The investigators assigned members to each condition on the basis of time entering the study and did not include a control group in their study design. Both treatment groups evidenced significant clinical improvement over 9 months of therapy. Of the 13 subjects who dropped out of treatment before the end of the 9-month period, 10 showed improvements in depression on the HAM-D, with mean improvement being 34%. There were no differences between treatments on the clinician-rated Hamilton Rating Scale (HAM-D), although the CBT group had lower scores on the self-report Beck Depression Inventory (BDI).

Lynch *et al.*[66] have reported unpublished pilot work using dialectical behavior therapy (DBT) skills training to treat elderly depression. Twenty-seven participants were randomly assigned to DBT skills training plus medication *or* medication alone plus clinical management. All participants were on antidepressant medication and all met criteria for MDD at baseline. DBT included weekly 2 h group skills training and weekly half-hour telephone check-in calls by a therapist for 28 weeks. Approximately 29% of the sample met strict criteria for a SCID-II diagnosis of personality disorder. Although there was a trend for DBT patients to show lower desires to please others from pre- to post-treatment relative to medication alone, there were no significant differences between treatments on outcome measures. Both DBT and medication alone showed significant reductions in HAM-D and BDI scores. Within-group analyses revealed that the medication alone group showed significant improvement over time *on only one* variable that the DBT condition did not, namely fear of sadness. The DBT condition showed: significant decreases in hopelessness and in total adaptive, avoidant, detached, and emotional coping; significantly lower sociotropy/dependency; lower desires to please others; and lower autonomy scores from pre- to post-treatment.

MAINTENANCE THERAPY AND RELAPSE PREVENTION

Despite the effective treatments available for depression in the elderly, it has been established that elderly patients who recover

from an episode of major depression are at high risk for relapse. Reynolds *et al.*[8] used a combination of medication and psychotherapy for the acute treatment of depression in order to empirically test the most effective maintenance therapy for remitted elderly. In their study, the 107 patients who fully recovered in open acute treatment with nortriptyline and interpersonal therapy were randomly assigned to one of four maintenance therapies: nortriptyline and IPT; nortriptyline and medication clinic; placebo and IPT; or placebo and medication clinic. Combined psychotherapy (IPT plus medication) was superior (80% effect) to medication alone (57% effect), psychotherapy alone (43% effect) or placebo (10% effect) for the maintenance of treatment gains and prevention of relapse. Reynolds *et al.*[8] concluded that combined psychotherapy and medication treatment appears to be the optimal long-term strategy in preserving depression remission and recommended that all older patients with recurrent depression be referred for psychotherapy. Research is currently under way testing the hypothesis that combination treatment is the most cost-effective way to treat recurrent depression in the elderly.

TREATMENT-RESISTANT POPULATIONS

While Reynolds and colleagues have established that combination therapy is the preferred means for maintenance of remission, there is an alarming number of elderly depressed patients who do not respond to medication, psychotherapy or the combination. Although acute remission rates of 50–70% are impressive, there remains another 30–50% of patients who do not respond. It has been found that elderly patients with co-morbid personality disorder, irrespective of level of depression, are less likely to benefit from short-term therapy than patients without co-morbidity[67] (see review[68]); hence, part of the population not responding to treatment may have personality disorders. However, with the exception of case studies, no outcome study has specifically focused on treating late-life personality disorders, and those studies reporting outcomes for personality-disordered elderly have suffered from varied methodological problems[68]. Nevertheless, poorer outcome and increased likelihood of relapse among personality-disordered elders, as well as continued observations that depression in the elderly is often a recurring phenomenon, require that revisions to existing treatments be made and implemented.

DYSTHYMIA

Despite the growing interest in studying treatment of depression in the elderly, we did not find any research specifically investigating the treatment of dysthymia in elderly patients. Although the research on treatment of recurrent old-age depression[8] may reflect issues associated with treating dysthymic individuals, research protocols up to now have focused primarily on a diagnosis of major depression. However, minor depression or less severe forms of depression remain important areas of investigation. Partial responses to treatment are associated with higher rates of relapse[69] and minor depression is more prevalent than MDD and subsequently has a greater number of disability days associated with it[70]. In addition, researchers have found that patients with endogenous depression (an older term with a symptom profile similar to dysthymia) responded less favorably to psychotherapy than non-endogenous depression patients, and that improvement occurred more quickly for the non-endogenous subtype[57]. Thus, more research is needed to examine the public health challenges posed by old-age chronic recurring depressive experience, partial responses to treatment, and minor depression.

CONCLUSIONS

There is a growing body of research demonstrating that psychotherapy offers significant promise for the treatment of elderly depression, preventing depressive relapse, and at times may be the preferred treatment modality in terms of both efficacy and patient choice. Referral to psychotherapy remains a problem, and current research on underdiagnosis and under-treatment of depression in older adults focuses more on describing the problem than on understanding it. However, with more insight into the reasons *why* elderly depression is inadequately diagnosed and treated, health providers can begin to develop operative means to ensure that this disabling yet treatable disorder is not ignored. General practitioners and mental health professionals do have the means to treat depression in the elderly with medication and/or psychotherapy; the work now lies in getting out into the "real world" and putting these techniques into practice.

Long-term Management of Affective Disorders

Mohammed T. Abou-Saleh
St George's Hospital Medical School, London, UK

Depressive illness is a public health problem. One in five individuals will suffer from one form of depression or another, four-fifths of those will suffer further episodes of illness and a fifth will die by suicide or cardiovascular disorders. Affective disorders are the most commonly diagnosed psychiatric conditions in the elderly in both general and hospital practice. Their incidence and prevalence increases with age, particularly in their more severe forms, with endogenous and psychotic features. It would be true to say that non-bipolar depressive illnesses with endogenous and psychotic features are essentially illnesses of old age. Depressive illnesses are often recurrent and are associated with high continuing morbidity and mortality. Their acute and long-term management is often successful and rewarding, with the availability of highly specific and effective physical and psychological treatments.

The focus of this chapter is on the strategies of long-term management of affective disorders, starting with a review of studies of their natural history and the usefulness of antidepressants and lithium as continuation and prophylactic therapies. Particular emphasis is laid on lithium therapy, its efficacy and safety, optimal dosage and dosage regimen and important aspects of its routine in psychiatric practice.

In essence, the usefulness of any treatment with established effectiveness also applies to the elderly with depressive illness, and the evidence marshalled to support the use of these treatments often derives from studies done on younger patients. In this chapter, reference will be made to whether the study was done on younger or older patients.

NATURAL HISTORY

Studies of the natural history of depressive illness in old age have been relatively few compared with studies in younger patients. The literature on both hospital and community-based studies have been critically reviewed[1].

Post[2] studied patients over 60 years of age who were followed up for a period of 3 years after discharge from hospital: a quarter of the patients had lasting recovery, whilst the other three-quarters were equally subdivided into a group who had recurrences and a group who continued to be ill over the entire study period. Factors that predicted poor outcome were age over 70 and a duration of illness of more than 2 years prior to admission. Blessed and Wilson[3] reported a 2 year follow-up study of a hospital cohort: one in five of their patients with affective psychosis had either not been discharged or had been re-admitted within the follow-up period. In a similar study, however, Christie[4], found that only 6% of the patients were still in hospital within the 2 years of follow-up. The study by Murphy[5] involving patients over the age of 65, treated in a variety of settings and followed up 1 year later, found that 43% had recovered by 1 year and 57% either had an early relapse of illness or had not recovered. Predictors of poor outcome were increased severity of illness, the presence of physical illness, longer duration of illness and the occurrence of life events during the follow-up year. Ninety per cent of patients with delusional depression had poor outcome. The study by Baldwin and Jolley[6], using a similar methodology to that by Murphy[5], reported a more favourable outcome: 50% of patients were fully recovered, 15% had a relapse following recovery and 18% were continuously ill. Poor prognosis was predicted by being male with physical illness, but was not associated with delusions. Longer follow-up studies over 20 years, involving elderly patients with depressive illness, showed that three-quarters of patients had recurrences[7,8]. Remarkably, the study by Ciompi[8] found that only 11% were totally free from psychiatric symptoms and one-third of patients had chronic depressive illness.

The year 3 follow-up of 1070 persons aged 65 and over living in the community in Liverpool[9] showed that 72% of patients with depressive psychosis and 62% of patients with depressive neurosis were either dead or had some kind of psychiatric illness 3 years later.

In conclusion, these studies, despite differences in methodology and duration of follow-up, clearly indicate the high continuing morbidity of depression in old age: the majority of patients with depression occurring or recurring in old age will suffer further episodes of illness, with one-fifth to one-third of patients experiencing chronic illness, particularly those who present with more severe illness and those with physical conditions leading to high mortality by suicide and cardiovascular conditions (see Chapters 83, 87 on suicide and prognosis, this volume).

ACUTE MANAGEMENT

Acute management of depression in old age is often successful and rewarding, with the introduction of highly effective and specific treatment. In his review of the efficacy of antidepressants in elderly patients, Peet[10] concluded that efficacy is established for drugs such as imipramine, amitriptyline, nortriptyline, phenelzine and mianserin with placebo control. Of the new antidepressants, trazodone and bupropion also show convincing efficacy in comparison with placebo. About two-thirds of patients respond well to these antidepressants. The effectiveness of psychological treatment in the acute management of depression in the elderly has not been satisfactorily established (see Chapter 79). However, reference is made to studies done on younger patients. A recent

study from the National Institute of Mental Health (NIMH)[11] established the efficacy of brief interpersonal psychotherapy in comparison with standard treatment with imipramine plus clinical management, particularly with patients who are more severely depressed and functionally impaired. Cognitive–behavioural therapy (CBT) was found to be less effective than these two treatments when compared with placebo plus clinical management. This study was the first comparative study of the effectiveness of interpersonal psychotherapy and CBT. Its results, however, are disappointing to those who advocate the supremacy of CBT for the treatment of depression in general and hospital practice. However, there is evidence for its long-term effectiveness in preventing relapses or recurrences of illness[12]. The evidence for the efficacy of antidepressants (26 RCTs) and psychological treatment (RCTs) in older adults with depression has been critically reviewed[13]. Compared to placebo, efficacy has been established for fluoxetine, trazodone and phenelzine but no evidence for the superiority of any antidepressant over any other. In depressive patients with physical illness (18 RCTs), antidepressants were more effective than placebo. For psychological treatments in 40 controlled trials, treatments (cognitive therapy or CBT) were shown to be more effective in mild to moderate depression. However, these treatments were no more effective than non-specific attention.

The evidence for the efficacy of electroconvulsive therapy (ECT) in the severe forms of depression is overwhelming, although this derives mainly from studies done on younger patients. Of note was that the only predictor of good response to real vs. simulated (sham) ECT is the presence of delusions. There is, however, a high rate of relapse following recovery by ECT, indicating the need for continuation treatment following recovery. Post[2], in his 3 year follow-up study of depressed elderly patients, noted that 75% of patients relapsed when dosages of antidepressant were lowered after 3 months, and that it had been possible to discontinue treatment permanently in only 18% of patients; 38% of patients required tricyclic antidepressants (TCAs) intermittently or continuously and others had to be given lithium or had a further course of ECT. The study by Murphy[5] had no patients on prophylactic lithium.

Continuation Therapy Following ECT

The efficacy of ECT in the management of depression in old age is often compromised by the high relapse rate following recovery. Abou-Saleh and Coppen[14] critically reviewed the evidence for the efficacy of continuation therapy with antidepressants and lithium following recovery with ECT. It was shown that in four prospective placebo-controlled studies over a period of 6 months to 1 year, these drugs substantially reduced the relapse–recurrence rates during follow-up. The conclusion was that lithium would be particularly effective in those with delusional depression, bipolar depression and in the elderly.

LONG-TERM MANAGEMENT

Long-term management occurs in two phases: a continuation therapy phase to prevent early relapse of illness and a maintenance–prophylactic phase to prevent recurrence (Figure 80.1). Studies of the value of continuation therapy after recovery have established the efficacy of antidepressants and lithium in preventing relapse of illness. Continuation therapy with drugs appears to reduce the relapse rate by half compared to placebo within 4–6 months from recovery from the acute illness[13].

The American Psychiatric Association Guidelines[15] recommend antidepressant continuation therapy for 16–20 weeks following remission, using the dose used in the acute phase. There is also evidence to support the use of specific psychotherapy during the continuation phase. The patient's clinical condition, as well as the specific treatment being provided, determine the frequency of visits. The decision to discontinue treatment should be based on the factors considered in the decision to initiate maintenance treatment, including the probability of recurrence, frequency and severity of past episodes, the persistence of dysthymic symptoms after recovery, the presence of co-morbid disorders and patient preference, in addition to consideration of the benefits and adverse effects of maintenance treatment.

In a number of controlled investigations of variable stringency, TCAs and lithium were shown to reduce the long-term morbidity and mortality in patients with unipolar illness, including the elderly. The results of these studies have, however, been disappointing, with only 48% success rate (absence of a relapse–recurrence) in the NIMH study with imipramine maintenance therapy over 2 years. The Medical Research Council study showed a success rate for amitriptyline of 32% over a period of 3 years' maintenance therapy[16].

Prophylactic Treatment

Early studies indicated a poor outcome of late-life depression[5], with high relapse, recurrence and chronicity. This view was based on naturalistic observation without monitoring the compliance, adequate dosage and duration of treatment, including prophylactic treatment, and was therefore challenged[17]. Controlled studies of maintenance antidepressant medication, however, showed better outcome for late-life depression[18]. The Pittsburgh group reported a 3 year follow-up study of maintenance treatment with nortriptyline or placebo, with or without interpersonal psychotherapy (IPT)[19] and showed that 80% of patients assigned to nortriptyline, with or without IPT, remained in remission. The Pittsburgh group also identified the elderly patients who remained well after placebo-controlled discontinuation of antidepressant medication for a period of 1 year. Recovery of good subjective sleep quality by early continuation treatment was useful in identifying which remitted elderly depressed patients remained well with monthly IPT after discontinuation of antidepressant medication[20]. Moreover, effective maintenance treatment with nortriptyline was associated with enhancement in the rate of delta-wave production in the first non-rapid eye movement (REM) sleep and of REM activity throughout the night[21].

A recent study of the effects of treatment on the 2 year course of late-life depression[22] showed a 74% survival rate without relapse. This good outcome was obtained by the use of full-dose antidepressant medication, frequent follow-up and rigorous treatment of relapses. In a prospective 1 year uncontrolled study in elderly depressed and dysthymic patients, reboxetine was shown to be effective and well tolerated[23].

The US National Institute of Mental Health consensus statement update[24] concluded that recent evidence supports the recommendation for at least 6 months of treatment beyond recovery for those with first onset in late life, and for at least 12 months for those with a recurrent illness[25]. Moreover, prophylactic treatment should be of the same type and of same dosage as that which was successful in the initial acute phase. The consensus statement also concluded that treatment response and long-term outcome for all patients is generally similar to that observed in younger adults, but the temporal course may somewhat be slower in the elderly and risk of relapse somewhat greater[24]. The use of lithium in continuation and prophylactic treatment of depression in the elderly has also been recommended[18,26], with the use of lower doses/plasma levels. Lithium may be a more favourable prophylactic treatment than antidepressants in recurrent

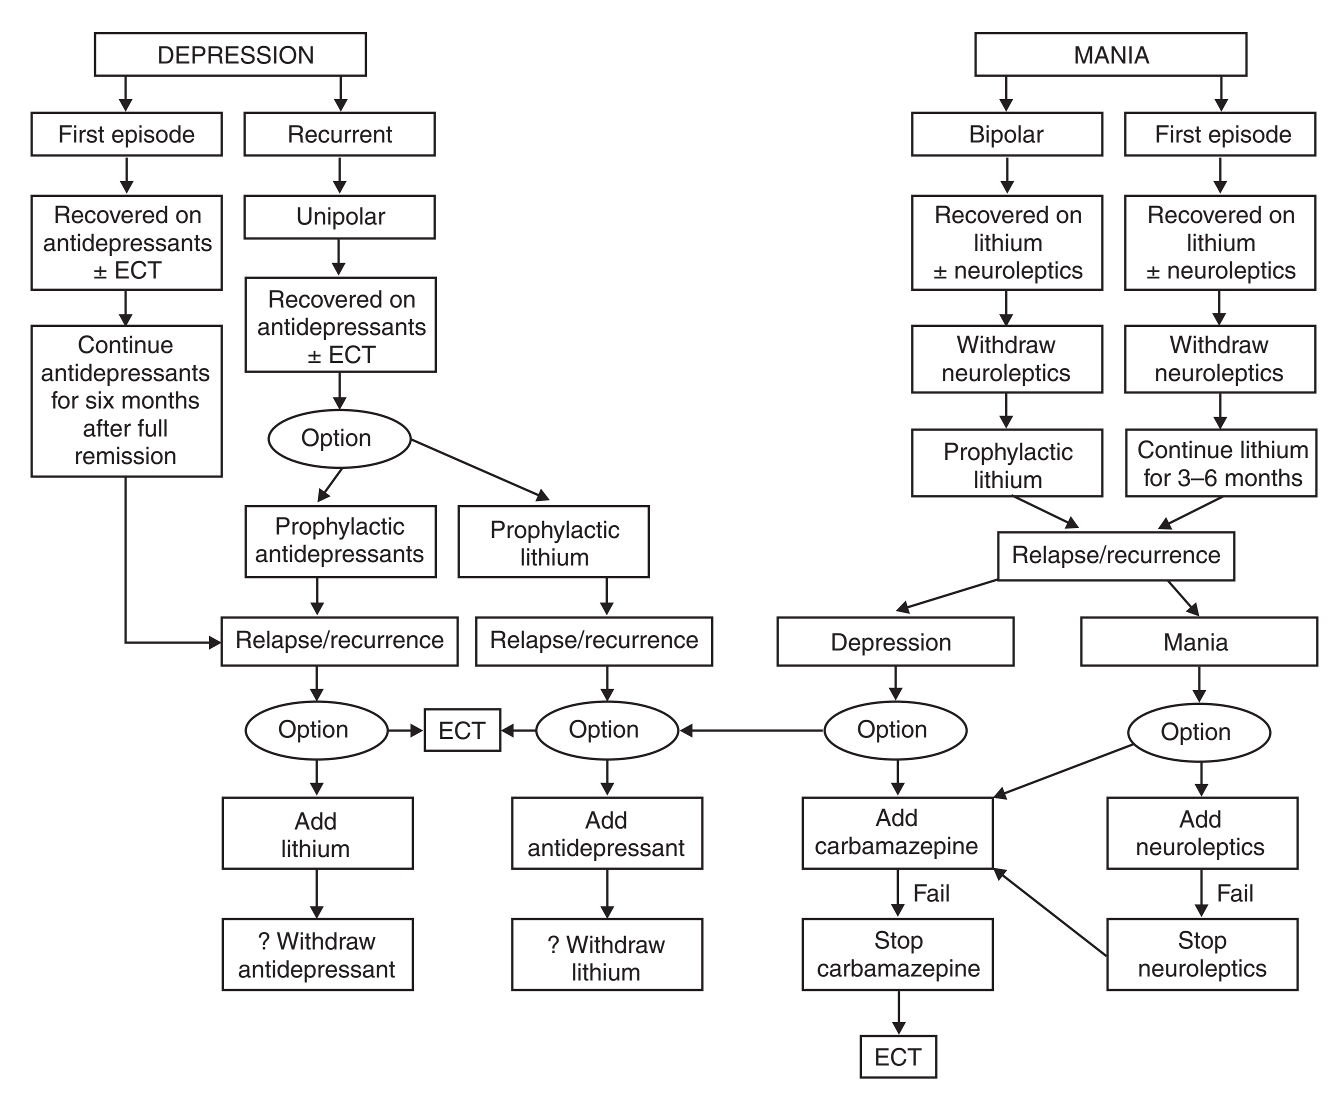

Figure 80.1 Long-term management of depression and mania

depression with melancholia and in depression with psychotic features (delusional depression), which are particularly common among the elderly, with a tendency to respond less well to antidepressants[17]. The other advantage of lithium therapy is the evident decreased mortality, whether from suicide or other causes[27]. A recent 1 year prospective, placebo-controlled study of maintenance lithium in conjunction with CBT in elderly depressed patients[28] showed that, although CBT reduced depression severity during follow-up, lithium therapy was no better than placebo. This appears to be related to poor compliance, a finding that highlights the serious difficulties in undertaking prophylactic studies in elderly depressed patients.

Lithium Therapy

The use of lithium in the management of affective disorders has proved to be one of the most rewarding therapeutic strategies in medical practice. In the management of bipolar disorders, it has provided one of the most specific psychotropic drugs in psychiatry. Lithium is the treatment of choice for mania and has comparable efficacy to neuroleptics, except in disturbed and agitated manic patients, who respond more dramatically to neuroleptic medication. The advantage of lithium, however, is that patients do not complain of the "strait-jacket" effect they experience with neuroleptics. Moreover, intermittent exposure to neuroleptics has been shown to be associated with a high incidence of tardive dyskinesia, particularly in the elderly, who are often less tolerant of neuroleptics and more commonly develop parkinsonian side effects. Lithium is also strongly recommended for the treatment of bipolar depression, rather than tricyclics, which may provoke hypomanic episodes and increase the risk for the development of rapid-cycling illness. There is evidence that lithium alone is effective in depression that has failed to respond to tricyclic medication, and in combination with other antidepressants in the management of resistant depression (see below).

Affective disorders are recurrent illnesses and the discovery of the prophylactic effects of lithium opened a new era in their management. In a number of controlled investigations of varying

stringency, done mostly on younger patients, lithium was shown to substantially reduce the long-term morbidity of both unipolar and bipolar disorder[14,29]. Prospective controlled studies showed that lithium was superior to placebo and tricyclics in the prophylaxis of bipolar illness. The majority of studies evaluating its prophylactic efficacy in unipolar illness found it superior to placebo, as effective as imipramine or amitriptyline, and more effective than mianserin and maprotiline. This may be related to the greater heterogeneity of unipolar illness.

Treatment of Bipolar Disorder

Elderly patients with late presentation or late-onset mania respond well to standard antimanic treatment with neuroleptics, lithium and anticonvulsants[30,31]. Neuroleptic treatment is best avoided in the elderly because of its known extrapyramidal side effects, except for floridly psychotic, agitated and behaviourally disturbed patients, who need rapid control of symptoms. Lithium remains the treatment of choice, followed by valproic acid[30]. The evidence for the efficacy of lithium in late-life mania is based on retrospective and uncontrolled studies, and there have been no controlled studies of the efficacy of anticonvulsants in late-life mania. It has been suggested that valproate is a safer alternative treatment to lithium than carbamazepine, whether used as single or adjunct treatment in elderly manic patients[30,31]. There are no guidelines regarding the optimal plasma concentration of valproate in relation to efficacy[30].

A recent evidence-based review of the treatment of mania, mixed state and rapid-cycling illness in younger populations[32] concluded that lithium and divalproex sodium are effective in mania, whereas divalproex sodium and carbamazepine are more effective in mixed states. Divalproex sodium is the drug of choice for rapid-cycling disorder. With bipolar depression, lithium is recommended as a first-line treatment and the addition of a second mood stabilizer or a TCA would be an appropriate next step[33].

The guidelines for the continuation and prophylactic treatment of bipolar illness in late life are similar to those advocated for younger patients, except for the notion of high recurrence rates necessitating prophylactic treatment even after a first onset manic episode. Three sets of guidelines for the treatment of patients with bipolar disorder were reviewed[35]: the American Psychiatric Association Practice Guideline[15], the Expert Consensus Guideline Series (1996) and the Clinical Practice Guidelines for Bipolar Disorder from the Department of Veterans Affairs[36]. Lithium remains the medication of choice for prophylaxis. A comparative audit of the prevalence of lithium therapy and the quality of monitoring in over-65s in Cambridge and Southampton showed a wide variation and indicated that a dedicated monitoring service leads to a better quality of treatment supervision[37].

Who Responds to Prophylactic Lithium?

Response to lithium varies between complete, with no further episodes of illness, to partial, with the frequency and severity of episodes reduced, to failure to respond, when morbidity continues unabated. Overall, 50–70% of patients with bipolar and severe unipolar illness show favourable responses to lithium, with a small minority who are total non-responders. The latter are often patients with rapid-cycling bipolar illness (those who suffer four episodes of illness per annum or more). The main reasons for failure of prophylaxis are poor compliance and side effects such as weight gain, increased thirst, difficulties with memory, poor concentration and loss of enthusiasm.

A recent study examined the clinical and psychological characteristics of elderly patients receiving prophylactic lithium in relation to long-term outcome of treatment (Abou-Saleh, unpublished). Elderly patients with bipolar illness had better outcome than those with unipolar illness. In their personality characteristics, those who had an excellent response showed higher scores on extraversion and energy output than those who responded less well. The most powerful predictor of long-term response, however, was their response during the first 6 months of therapy, confirming the results obtained in younger patients[34].

Treatment Compliance

Compliance with treatment is a major problem in the elderly. A study by Johnson[38] showed that the dropout rate from a group of depressed patients treated in general practice increased from 16% at the end of the first week to 68% at the end of 1 month. This was related to doubts about the benefits and less related to the occurrence of side effects. Of particular importance are the cognitive and sensory impairments of the elderly, low motivation, and poor communication by doctors of the benefits and risks to patients and their relatives. In the background lurks a nihilistic attitude and doubts about the effectiveness of treatment in both patients and doctors.

Prophylactic Lithium in the Elderly

Himmelhoch[39], in an open study of the efficacy of lithium in elderly patients, reported a favourable response rate in two-thirds of these patients. The majority of poor responders, however, had neurological conditions, which probably impaired the efficacy of lithium. The present author reported the results of a series of open and controlled studies of the efficacy of lithium in conventional and lower doses in the prophylactic management of affective disorders in old age[40]. In the Lithium Clinic at the Medical Research Council Neuropsychiatry Laboratory in Epsom, UK, 44 male and 104 female patients with affective disorders were followed up for a period of 1–14.5 years (mean 4.9 years). They all received a slow-release lithium preparation at bedtime. Plasma lithium concentrations were maintained at 0.8–1.2 mmol/l 12 h after dosing. Prophylactic lithium was started in 47 of these patients after 60 years of age. There was no significant difference in the Affective Morbidity Index (a composite index of severity and duration of affective episodes) between the younger and these elderly patients, as shown in Table 80.1. Side effects in the older group were similar to these in younger patients. In a further study[34], 22 elderly patients over 60 years of age who started lithium in late life received 25–50% reduction in lithium dosage in a double-blind situation. The elderly group of patients fared as well on lower doses of lithium as younger patients and had a significant reduction in subjective side effects, such as tremor and thirst (Table 80.2). However, results for the whole group, with a majority of younger patients, showed that a reduction of 50% in daily dosage was safe: patients who had the reduced dose of lithium and plasma lithium levels of 0.45–0.59 mmol/l showed reduced morbidity during the year of follow-up, compared with the year preceding the trial, and showed fewer subjective side effects and adverse effects on thyroid and renal function.

Side Effects

Subjective Side Effects

The occurrence of subjective side effects during lithium therapy is well documented[41]. Side effects in the early stage (within 6 weeks

Table 80.1 General details of patients and relationship between age and morbidity during lithium therapy (results expressed as mean ± SEM)

Age when lithium started (years)	n	Episodes prior to lithium	Years on lithium	AMI[b]
>60	47	4.9 ± 0.6	3.8[a] ± 0.4	0.18 ± 0.03
40–60	79	4.2 ± 0.3	5.5 ± 0.4	0.17 ± 0.02
<40	22	4.4 ± 0.6	5.3 ± 0.7	0.14 ± 0.03

[b]Affective Morbidity Index.

Table 80.2 Morbidity and plasma lithium level in 22 elderly patients before and during trial period (results expressed as mean ± SEM)

Plasma lithium level (mmol/l)	n	AMI	
		Before trial	During trial
>0.8	8	0.16 ± 0.08	0.17 ± 0.06
0.60–0.79	6	0.40 ± 0.17	0.36 ± 0.12
0.45–0.59	8	0.22 ± 0.15	0.36 ± 0.20

of starting lithium) include nausea, loose stools, fatigue, muscle weakness, polydipsia, polyuria and hand tremor.

During maintenance, weight gain, mild memory impairment and hand tremor are common complaints and polydipsia and polyuria may persist. The rate of occurrence of these side effects and their severity is related to plasma lithium concentrations. The elderly are particularly vulnerable to side effects. Smith and Helms[42] examined the incidence and severity of side effects in elderly patients receiving lithium in comparison with younger patients. Whilst there was no difference in the total incidence of side effects, there was a trend for more serious side effects to occur more frequently in the elderly: 33% of the elderly experienced "confusion" vs. 12% of the younger group. Worthy of note is that the patients were maintained on relatively high plasma concentrations for this age group, 0.86–1.26 mmol/l. Patients with neurological conditions (parkinsonism and facial dyskinesia) develop neurotoxicity at relatively low plasma levels of less than 0.65 mmol/l[39]. In a recent investigation, Coppen and Abou-Saleh[26] reported that prevalence rates of subjective side effects in elderly patients receiving low-dose lithium (plasma lithium levels of 0.52–0.6 mmol/l) were similar to those of younger patients maintained on similar plasma levels.

Thyroid Effects

Elderly patients on prophylactic lithium are more likely to develop hypothyroidism than younger ones and women are more susceptible than men. This may be related to the increased disposition of women to develop autoimmune thyroid disease in middle and old age. Indeed, pre-existing thyroid disease is the major vulnerability factor for the development of hypothyroidism during lithium therapy. Coppen and Abou-Saleh[26] studied thyroid function in 125 patients receiving low-dose plasma levels of lithium. Women had significantly higher levels of thyroid stimulating hormone (TSH) than men, and all four patients with abnormally high TSH levels were unipolar women. Of the 11 patients who received replacement thyroxine, 10 were unipolar patients. Thyroid function has been related to increased affective morbidity during receipt of prophylactic lithium and has been implicated in the development of rapid-cycling bipolar disorder.

Renal Effects

Overall, 5–10% of patients on prophylactic lithium develop tubular kidney damage complicated with glomerular pathology. There is no evidence that these changes are conducive to renal insufficiency, which rarely occurs in patients who have suffered lithium intoxication or had pre-existing renal disease. Lithium dose requirements show a decrease with age, which could be accounted for by the age-dependent fall in glomerular filtration rate and lithium clearance. With age, there is a decrease in muscle mass, which limits the value of measuring serum creatinine levels as an indicator of renal function. Age-related decrease in the volume of distribution of lithium also contributes to higher plasma levels in the elderly. The daily dosage of lithium required to achieve a given plasma level may be half the dose required for a younger patient. A number of studies have evaluated renal function in relation to the dosage regimen, comparing a once per day dosage regimen to a twice-daily regimen. Contrary to the conventional wisdom, of avoiding higher peak plasma levels associated with a single daily dosage regimen, this regimen was found to be safer for renal function than a divided daily dosage regimen: functional and structural abnormalities were more pronounced in the group of patients who received lithium in divided doses than those who received it in the single daily dosage regimen, suggesting that it may be more important to have regular periods with lower levels than it is to have lower peaks.

Optimum Plasma Levels

In an open trial of lithium in elderly patients with mania (age 65–77 years), two-thirds of patients responded at levels of 0.52–0.8 mmol/l (mean 0.58 mmol/l). Two weeks after obtaining that range, two patients developed neurotoxicity and two patients only responded when the levels were raised to 0.9 mmol/l[44]. Several retrospective and prospective controlled trials have evaluated the efficacy and safety of variable lithium dosage levels in bipolar and unipolar disorder[45]. Some of these studies have included elderly patients. Overall, the minimal effective lithium level of the majority of patients is 0.4–0.8 mmol/l. Bipolar patients may require higher dosages/levels than unipolar patients[46]. It is evident that lower dosages/levels are associated with less severe subjective side effects and adverse effects on thyroid and renal function. A prospective open study examined the ongoing morbidity of 128 patients with unipolar, bipolar and schizoaffective disorders maintained at low doses of lithium (mean level 0.56 mmol/l) over a period of 1 year[26]. Affective morbidity was measured for three age brackets: <60 years; 66–70; and >70 years. Elderly patients aged 70+ had remarkably less morbidity than the two younger groups, but similar side effects (Table 80.3).

Shulman *et al.*[48] followed up 43 elderly patients (mean age 74 years) maintained on 12-hourly lithium levels of 0.5 mmol/l for an average period of 2 years. The majority of patients responded well to lithium, which was well tolerated, and compliance was excellent. The most common side effects were hand tremor in one-third of the patients and polyuria or polydipsia in one-quarter.

Lithium Interactions

Special consideration should be given to lithium interactions with drugs commonly prescribed for the elderly. Lithium may interact

Table 8.3 Affective morbidity and side effects in patients on lithium, divided according to age (results shown as mean ± SEM)

Age (years)	*n*	AMI	BDI[a]	Side effects
< 59.9	61	0.16 ± 0.02	6.3 ± 0.9	8.8 ± 1.0
60.0–69.9	51	0.14 ± 0.02	5.8 ± 0.7	8.7 ± 1.3
> 70.0	16	0.06 ± 0.01[a]	6.9 ± 1.7	7.6 ± 1.4

[a]Beck Depression Inventory.

with β-blockers, resulting in the slowing of heart rate, and similar interactions have been noted when lithium is combined with digoxin, with reports of increased risk of sudden cardiovascular death on this combination in predisposed patients. The elderly, however, are commonly prescribed thiazide diuretics for hypertension, which reduce lithium clearance and increase plasma lithium levels by reducing plasma volume, causing an increase in lithium and sodium reabsorption. This interaction is not observed with potassium-sparing diuretics and loop diuretics, such as frusemide. Amiloride, however, has been used for treating lithium-induced polyuria and diabetes insipidus. Finally, the widely used non-steroidal anti-inflammatory drugs have been reported to reduce lithium clearance and increase plasma levels, except for aspirin and sulindac. Ibuprofen was shown to cause significant decrease in renal lithium clearance and was linked to cases of lithium intoxication. Indomethacin, however, has been used to treat lithium-induced polyuria.

CONCLUSION

Good management calls for a comprehensive reassessment of the patient's condition to review diagnosis and to identify the reasons for treatment failure by a diligent assessment of the adequacy of previous treatments.

With regard to therapeutic strategies, these involve two concepts: alternative and adjunct therapy (Figure 80.1). The adjunct approach takes primacy over the alternative treatment approach. Adjunct treatments include lithium[49,50], folate and T4/T3, and also cognitive or interpersonal psychotherapy. Alternative basic treatment involves changing the conventional antidepressant to a new one, such as a selective serotonin reuptake inhibitor (SSRI) or the use of ECT. In mania, adjunct or alternative treatments are essentially anticonvulsants, principally valproate added to lithium or neuroleptics.

GUIDELINES FOR LONG-TERM THERAPY IN THE ELDERLY

The long-term management of recurrent affective disorders in the elderly starts with a careful assessment of the patient's psychiatric, physical and social condition. This involves full psychiatric examination and physical investigation for careful diagnosis, including the pattern of symptoms, previous episodes and their nature and treatment. Patients who have recovered from an acute episode of illness should be maintained for a minimum of 6 months at the same dosage, and those with a delusional first episode in late life, or who had recurrent (minimum of two episodes in 5 years) illnesses, should be considered for prophylaxis with antidepressants or lithium. The choice of antidepressant will depend on the physical condition of the patient. Conventional antidepressants should only be considered for the physically well. Otherwise, the new generation of antidepressants, including the SSRIs, should be considered. Lofepramine, fluoxetine, fluvoxamine, paroxetine and sertraline are safer antidepressants, with no cardiotoxic effects. Fluoxetine and sertraline have been successfully evaluated as maintenance and prophylactic treatments. It is prudent to start with low doses and build up the dose gradually, with careful monitoring of side effects. Lithium is particularly effective in bipolar illness and in delusional unipolar illness, either given alone or as an adjunct in those who are already receiving antidepressants with incomplete response. Carbamazepine and valproate is a useful adjunct in bipolar patients who have failed to respond to lithium. ECT is a highly effective treatment for relapses–recurrences, whilst continuing on maintenance or prophylactic medication. The elderly require regular follow-up, to monitor their physical, psychiatric and social conditions and to deal with any emergent problems and complications, with careful attention to their social network.

Laboratory Diagnosis: Dexamethasone Suppression Test

Mohammed T. Abou-Saleh
St George's Hospital Medical School, London, UK

There is little doubt that the application of the dexamethasone suppression test (DST) for the management of depressive illness has provided one of the most dramatic developments in biological psychiatry. Extensive investigations of this test began in the late 1960s and culminated in its introduction as a highly specific diagnostic test for endogenous depression[1]. There have been hundreds of studies on its use in diagnosis, in management and as a paradigm for investigating the pathophysiology of depressive illness.

Carroll[2] proposed that the DST was a highly specific diagnostic test for endogenous depression, with a specificity of 96% and a sensitivity of 50%. This claim has not been substantiated by other investigators, who reported high rates of non-suppression in a variety of psychiatric conditions, including non-endogenous depression[3], dementia[4], schizophrenia and alcoholism[5]. Abnormal DST results have also been obtained in mania[6] and eating disorders[7]. These findings have been repeatedly confirmed by other investigators and the clinical utility of the DST in the diagnosis and management of depression has been critically reviewed[1].

METHODOLOGICAL CONSIDERATIONS

Most studies have used the overnight DST, with 1 mg dexamethasone administered before midnight for cortisol estimation at 4 p.m. the following day. A cortisol of 50 ng/ml and above is taken as the criterion for non-suppression. A number of methodological aspects have been investigated, including sampling time, dexamethasone dose, the cortisol criterion for non-suppression, the assay technique and the bio-availability of dexamethasone. The criterion for non-suppression has been empirically determined by trading off the test's sensitivity and specificity, aiming for a specificity of over 90% and a sensitivity of 50%. Carroll's criterion of 50 ng/ml for non-suppression has been universally adopted, in spite of the great variation in sensitivity and specificity achieved in various centres.

Perhaps the most important contributing variable to the DST results is the dose of dexamethasone administered: the 1 mg DST has higher sensitivity and lower specificity than 2 mg DST. A corollary of the dose of dexamethasone is the corresponding plasma concentration achieved and its relationship to the results of the dexamethasone test: levels of dexamethasone in non-suppressors are lower than in suppressors[8]. The extent to which differences in bio-availability of oral dexamethasone account for differences in sensitivity and specificity of the DST for depression is variable. The application of dexamethasone "windows" could reduce this source of test variance[8]. Dexamethasone metabolism is influenced by liver function in males and by body mass in females[9]. The combination of DST with corticotropin releasing factor has been shown to be more closely associated with hypothalamic–pituitary–adrenal (HPA) activity than DST in depressed and normal subjects[10].

The influence of non-specific factors on the results of the DST has been reviewed[1]; factors studied included the degree of stress, ageing, the presence of physical illness, marked weight loss, and the effects of administration and withdrawal of psychotropic drugs.

An association between increasing age and non-suppression has been shown in depressive and demented patients and in normal controls[11]. However, a longitudinal study in elderly normal subjects followed up for a period of 2.5 years showed no effect of age and suggested that genetic factors may influence the set point of the HPA axis[9]. Physical illness is associated with non-suppression, particularly diabetes mellitus and hypothalamic disorders.

The list of drugs that interfere with the DST has been increasing, and includes hormonal preparations, liver enzyme-inducing drugs such as barbiturates, anticonvulsants and alcohol. Test results are not affected by normal doses of benzodiazepines, antidepressants and neuroleptics. High doses of benzodiazepines have been associated with normal suppression. The effects of withdrawing psychotropic medication have also been studied, with higher rates of non-suppression being observed in patients who discontinued antidepressants, neuroleptics and benzodiazepines. These non-specific factors have important effects on test results and must be ascertained when the DST is carried out in the clinical situation. They have undoubtedly contributed to the considerable variation in the rate of non-suppression in normal controls and psychiatric patients.

DIAGNOSTIC VALUE

The claim that the DST is a highly specific diagnostic test for endogenous depression (melancholia) has not been substantiated. Rates of non-suppression in endogenous depression varied (18–81%), a variation that may be partly related to the criteria used to define endogenous depression. An early review found that in 12 out of 20 studies, significant increases in non-suppression rates were found in endogenous compared with non-endogenous depressives, with the Newcastle Scale providing

better discrimination than studies using the Research Diagnostic Criteria and DSM-III criteria[12].

The Research Diagnostic Criteria for distinction between endogenous and non-endogenous depression have been validated by the DST[13]. Mitchell[14] studied the DST in relation to the Core system (objective signs of psychomotor disturbance), Newcastle scale and DSM-III-R melancholia: all three definitions were associated with DST results. The Core index, but not the Newcastle scale, was associated with cortisol levels and dexamethasone levels after partialling out the effects of age and baseline cortisol levels. A meta-analysis of studies of the DST in relation to psychotic/non-psychotic depression (14 studies) and melancholic/non-melancholic depression (19 studies) reported a strong association of DST non-suppression and psychotic depression (64.1%) vs. non-psychotic depression (41%)[15]. The DST has good discriminating power between patients with severe psychiatric disorders, including major affective disorders, acute psychoses and dementia and patients with chronic conditions, such as dysthymic disorders (neurotic depression), chronic schizophrenia, anxiety, panic disorders and acute grief. The specificity of the test is higher in normal controls (93%) and lowest in manic patients (51%). It has satisfactory sensitivity and specificity for diagnosing secondary depression in patients with stroke. DST non-suppression after 3 months from acute stroke predicts the occurrence of depression 3 years later[16]. A review of nine studies reported a median sensitivity of 47% and specificity of 87%, suggesting the DST's utility for the evaluation of post-stroke depression[17]. However, an interesting feature is the higher rate of non-suppression in demented patients with depressive symptoms than in those without.

PROGNOSTIC VALUE

The prognostic value of the DST has been evaluated by examining the clinical outcome following antidepressive treatments in suppressors and non-suppressors, by examining changes in suppression status in relation to clinical change, and by evaluating differences in long-term outcome between non-suppressors who later converted to normal suppression and those who remained non-suppressors. Initial studies of the predictive value of the test indicated a more favourable response to antidepressant treatment in non-suppressors than in suppressors. Coppen *et al.*[18], however, failed to find a difference in therapeutic outcome between suppressors and non-suppressors, classified on the basis of the traditional cut-off point (50 ng/ml) for cortisol level, but found that non-suppressors had more favourable responses to both antidepressants and electroconvulsive therapy (ECT) when the criterion for non-suppression was taken as a plasma control concentration of 100 ng/ml and above. Non-suppression confers a small advantage (1%) over suppression in predicting a more favourable response to antidepressant therapy. DST status predicted improvement on nortriptyline, but not moclobemide or placebo[19].

Changes in DST status have also been examined in relation to long-term outcome: persistent non-suppression has been associated with a greater risk of relapse within several months of treatment. Depressive patients who continued to be non-suppressors had a relapse or a fatal outcome in 77% of cases, while only 19% of those who had a conversion to normal suppression had such outcome[20]. In depressive disorders, Coryell and Schlesser[21] recently reported DST non-suppression to be more powerful than clinical factors in predicting completed suicides: survival analyses over 15 years showed that the estimated risk for eventual suicide was 27% in those with DST non-suppression compared to 3% in those with normal DST. In elderly depressive patients, post-dexamethasone cortisol levels were associated with clinical improvement and high cortisolism (150 mg/ml), and predicted improvement in delusional depression[22]. In six out of nine studies, patients with DST non-suppression following ECT had a higher rate of relapse than suppressors[23]. The value of the DST in predicting outcome following discharge has also been investigated in patients with schizophrenia and mania: non-suppressors had a more favourable clinical outcome after 6 months, and those manic patients who became suppressors before discharge had better outcomes after discharge than those who continued to be non-suppressors. In patients with senile dementia of the Alzheimer type who had depressive symptoms and who were non-suppressors, a trial of citalopram, a highly specific 5-hydroxytryptamine (5-HT)-uptake inhibitor was associated with improvement in these depressive symptoms and normalization of the DST[24].

COMMENT AND CONCLUSIONS

The introduction of the DST for the investigation of the psychobiology of depression has been a landmark development in biological psychiatry: it has had unprecedented evaluation and has been shown to be one of the most reproducible findings in the search for biological markers for depression. The balance of evidence indicates that the overnight 1 mg DST, with one plasma cortisol estimation in the afternoon of the next day and a cut-off point of 50 ng/ml has satisfactory sensitivity for depressive illness and high specificity when its results are compared with those obtained in normal controls and patients with minor psychiatric conditions and chronic schizophrenia. The specificity of the test for depression is unsatisfactory in comparison with other psychoses, including mania, schizophrenia and dementia. The sensitivity of the test is highest for severe depression with endogenous/psychotic features, mixed affective states and depression in old age. The test has little value in predicting response to antidepressants and ECT but provides a useful monitor of clinical progress and is a good predictor of long-term outcome: continued non-suppression or reversion from suppression to non-suppression during treatment or follow-up is an ominous sign that indicates a greater risk of relapse in the months following treatment. The influence of non-specific factors on the DST is considerable. Factors such as age, stress, weight loss, alcohol misuse, administration of anticonvulsants, withdrawal of psychotropic medication, presence of diabetes mellitus and the bioavailability of dexamethasone are important contributing factors to the test results. These factors, however, do not account for the variation in test results that appear to be essentially related to the biological process underlying depression. The 2 mg test has greater specificity, but lower sensitivity, than the 1 mg test and its diagnostic and prognostic value requires further investigation. The DST is only an aid to diagnosis and prognosis, aspects that should be essentially based on careful clinical assessment. The abnormal result provides a "physical sign" indicating biological depression. The DST test, like any other laboratory investigation, may increase the diagnostic confidence of the clinical diagnosis, but could never replace careful clinical assessment. The test is particularly useful in the assessment of biological depression associated with neurotic disorders, personality disorders, grief reaction and physical illness. Moreover, the presence of this "physical sign" indicates the necessity for vigorous physical treatment, or at least the use of a combined physical–psychological approach to such conditions as agoraphobia, obsessional illness and grief reaction, and the test may be particularly useful in monitoring the course of the illness and predicting its long-term outcome. Patients who continue to be non-suppressors are likely to relapse following recovery, and to require more intensive follow-up and continuation or maintenance of prophylactic

medication. The test may also be useful in determining when to discontinue medication: continuing non-suppression may reflect continuing vulnerability or activity of the illness, in spite of apparent recovery, and medication should only be discontinued if the test results change to normal suppression. When using the test in clinical practice, it is important to assess the presence of confounding non-specific factors and to interpret the presence of this "sign" accordingly in guiding diagnosis and prognosis. The value of the test for the clinician, like the value of a new drug, can only be empirically determined by its trial in routine clinical practice.

THE DST IN PSYCHOGERIATRIC PRACTICE

The diagnostic and prognostic value of the DST is enhanced in the psychogeriatric setting. This is related to the higher prevalence of depressive illness, endogenous type, and delusional depressions in the elderly and hence the higher prevalence of DST non-suppression (higher sensitivity) in this population. This increased sensitivity, however, is slightly impaired by the influence of age *per se* on the performance of the test, lowering its specificity; i.e. 10–20% of normal elderly patients show non-suppression. Its specificity is even lower when performed in patients with dementia, who show similar rates of non-suppression to depressive patients, which renders the DST less useful in the differential diagnosis of depressive pseudodementia. Moreover, the contribution of physical factors, including the presence of physical illness and the influence of interfering medication, further impairs its specificity for the diagnosis of endogenous depressive illness. There is, however, evidence that DST non-suppression in dementia is related to the presence of concomitant depressive symptoms[4,25], suggesting the usefulness of treatment with antidepressant medication. The evidence for this is, however, inconsistent: other studies have found no association between non-suppression and concomitant depressive symptoms and treatment with antidepressant medication has not consistently improved these symptoms or normalized the abnormal DST[26]. Whether the DST has diagnostic and prognostic value in milder forms of depression, which are common in the elderly, remains to be investigated.

Bereavement

Robert J. Kastenbaum

Arizona State University, Tempe, AZ, USA

Advanced age and bereavement are circumstances, not psychiatric syndromes. An octogenarian may have a variety of concerns, such as remembering which medication to take when, fear of falling on icy pavement, and worry about remaining financially independent on a fixed income. A recently bereaved octogenarian is likely to have additional concerns: "Who can I share my day with?"; "Who will do the driving/cooking?"; "Where do I go from here?". These are all essentially human rather than geriatric problems. Therefore, the psychiatry of bereavement in old age does not assume pathology or the necessity for professional intervention. Hastily prescribing psychotropic medication for a "geriatric patient" can all too easily become part of the problem, rather than the solution. Instead, we ask ourselves such questions as, "Who is this person?"; "What was the nature of this unique relationship that has been ended by death?"; "What does this loss mean to the bereaved person—and what coping skills and resources can be called upon to make it through?".

A perspective on bereavement in old age can be developed by following the sequence of events and challenges. Fortunately, a growing number of clinical observations and research findings are available to guide this overview.

THE PRE-BEREAVEMENT SITUATION

Four questions are particularly useful in approaching an understanding of the situation that existed prior to a bereavement in old age.

1. What Was the Nature and Status of the Relationship at This Time?

This question should be answered both structurally and substantively, e.g. "He was her older brother; she relied on him for advice and support more than on any other person, including her husband"; or "She was his second wife; he had expected her to look after him—actually, to wait on him hand and foot!—and suddenly he had to be the caring person . . .". It is useful to explore both the affective and pragmatic dimensions of the relationship. Was the survivor or the deceased heavily dependent on the other person? Had the relationship been in serious trouble? If so, was this shown by silent coexistence or stormy disputes? Did the deceased provide most of the couple's link to society? Had the survivor organized his/her life around taking care of the deceased?

Particular sensitivity may be required in understanding an elderly person's response to the death of an adult child or a grandchild. Recent studies suggest a highly individualized deep interiorization of grief after the first shock of the loss[1,2]. There may be little apparent behavioral change but much continued inner processing of the loss and an intensified life review. Researchers are reaching consensus on the multidimensionality of the older person's response to bereavement and caution against simplistic characterizations, such as "depression".

2. How Was the Prospect of Death Integrated into the Life Scenario?

The possibility of *anticipatory grief* should be explored, rather than assumed. Fatal accidents (especially falls and motor vehicle accidents) are far more common among people 65 and older than in any other age group (in fact, data from the US Center on Health Statistics indicate that there are more fatal accidents at 65+ than in all other age groups combined). This means that many an elderly spouse or sibling has no opportunity to prepare for the death of a person who did not seem to be in imminent danger of death. Others may have coped so long with chronic health problems that it seemed as though they might continue to go on forever. Furthermore, obvious risks may have been strongly defended against by compartmentalization or other common mechanisms. The bereavement may also take the form of the completely unexpected death of a younger family member or friend.

Despite many exceptions, however, there is a greater probability that the death will have been expected. Not only do an increasing proportion of deaths occur in old age, but modern health care has lengthened the interval between development of a life-threatening condition and the day of death. The four leading causes of death for elderly people in the USA (heart disease, malignant neoplasms, cerebrovascular disease and respiratory conditions) all involve a long period of living with progressive life-threatening conditions and, therefore, opportunity for both prolonged stress and adaptation to the prospect of death. Anticipatory grief is similar in many respects to the grief that is experienced after a death[3]. There are affective, cognitive and somatic components, e.g. sadness, obsession, exhaustion, etc. Clinical experience suggests that a period of anticipatory grief often helps the survivor to cope with the loss, by avoiding the element of surprise and providing the opportunity for preliminary adjustment. Traumatic grief reactions are more common when bereavement is sudden and unexpected[4].

However, awareness of an impending loss is not an invulnerable shield against the first impact. "I thought I had cried all the tears there were to cry. I had myself under control", one woman reported. "Not a bit of it! I went all to pieces, feeling Sammy's hand so cold". We are beginning to learn that anticipatory grief

has both its advantages and its risks. Did this survivor start to detach him/herself emotionally while the spouse was still alive, depriving them both of the support they needed? Or did both partners use this time to affirm their love and consult with each other in making plans and decisions?

Physicians and other caregivers have the opportunity to make valuable contributions to the survivor's ability to cope with grief by sensitive response to the situation as it exists prior to the death. Offering accurate information, suggesting other options and improving the lines of communication within the family are among the ways in which one can help to shape the anticipatory grief period into a source of strength rather than intensified anxiety. The age differential between most caregivers and the elderly bereaved people they are trying to help sometimes interferes with communication, e.g. when elders are patronized and their ability to cope with bad news is underestimated. There is also an underappreciated connection between quality of terminal care and grief recovery. A hospice physician reports that, "The pain relief we achieve for an old man in his last weeks of life helps his wife to be more of her normal self when he really needs her—and a widow with fewer regrets and nightmares later"[5].

3. What Was the Survivor's Own Health Status Previous to the Bereavement?

This is a particularly useful question to ask with respect to the older bereaved person. The spouse was the most frequent principal family caregiver in the 40 hospices studied by Mor *et al.*[6]. About two-thirds of the spouses taking responsibility for care were people above the age of 55 and it was not unusual for the caregiver to be over 75. The elderly caregiver seldom developed new physical problems over the course of the spouse's final illness, but there was a tendency to ignore his/her existing conditions. During the first months of bereavement, the survivor's health was sometimes impaired by exacerbation of previous illnesses and impairments. It would be helpful, then, to encourage the spouse and other elderly family members and friends to look after their own health during the pre-bereavement period, and to see that health status is carefully assessed afterward. Symptoms that might appear to be part of an anxious depression syndrome could be related to physical health problems that have not received the attention they deserved.

4. Who Else Was There and What Else Was Happening?

Explored diligently, this line of inquiry may reveal significant sources of concern or potential strength that bear on adjustment to the loss. "Well, Frank's brother had come to live with us again. And he was drinking again. I could have killed him"; "The people from the church were over all the time. They really cared. We were so far from the rest of the family, but they were just like family to us . . ."; "I couldn't get anything from the doctor—what was really going on with George, what else I could do. I felt like telling him, 'I'm old—not stupid!', but you don't do that, do you?". Some of the problems that beset the survivors after the death may be the continuation or outcome of difficulties that occurred earlier. Strained interpersonal relationships and unanswered questions create more of a burden for some survivors than the death itself.

AT THE TIME OF DEATH

Learning what happened around the time of death can help us understand the bereaved elder's state of mind. Consider, for example, the difference between death at home and in a hospital setting. A terminally ill woman was being looked after at home by her elderly mother, with support from a local hospice service. The mother had accepted her daughter's wish to be allowed to die at home without intubation and other futile procedures. But when the daughter appeared to be actively dying, the mother panicked and called not the hospice but a visiting nursing service. Now, as a survivor, the old woman is haunted by memories of her suctioned, intubated and drugged daughter accusing her with her eyes[7]. In a more frequent scenario, an elderly person will call for assistance from paramedics when his/her spouse appears to have died. But when the paramedic team arrives, the caller may have second thoughts about seeing the spouse's body subjected to resuscitation procedures. Some bereaved elderly persons remain troubled not by the fact of the death itself, but by unanswered questions about whether or not they did the right thing at the right time.

Knowing only that the death took place in a hospital does not tell us whether supportive nurses encouraged a woman to be with her husband right through to the end and to have time with him afterward—or whether she was made to feel unwelcome and hustled away. Perhaps, again, she had not been notified until some time after the death. The particularities of the final scene can either provide an acceptable conclusion to the story of a marriage or friendship, or torment the survivor with resentment, self-doubt and other disturbing thoughts.

The psychiatrist often has the opportunity to increase the sensitivity of physicians, nurses, and other caregivers in their communication patterns around the time of death. Survivors may hold on to a word or a gesture, either as a cherished or an infuriating/depressing memory. Often one can be helpful simply by validating the survivor-to-be's feelings and giving him/her the opportunity to clarify his/her own thoughts by active listening. The generational difference between the bereaved person and the psychiatrist can be a source of misunderstanding. A widow, for example, may first respond according to the models of grief that were prevalent in her youth. It may take patience and encouragement to help her discover, express and cope with her own feelings. It is also helpful to be aware of ethnic differences in expectations for behavior around the time of death. Caregivers whose own tradition involves subdued behavior and restraint of emotions may not be prepared for families in which intense expressions of grief are expected, even required.

EARLY PHASES OF BEREAVEMENT

The idea that there are fixed "stages" of either dying or grief has attracted more believers than it deserves. One can select and force observations to fit stage theories, but to what purpose? Individual responses to grief deviate markedly from the models: this is even more common in old age, where uniqueness has been deeply engraved and polished to a high gloss.

It does make sense, though, to differentiate between responses to earlier and later periods subsequent to bereavement. Indicators of a potentially intense, disabling and protracted reaction often appear within a short time. Parke and Weiss[8] found that those who had the most difficult time coping with the spouse's death tended to smoke and drink more heavily, use tranquilizers and express depressive mood (e.g. "Life is a strain for me . . . I wonder whether anything is worthwhile any more"). These and other investigators have found that the way the survivor responds to the loss within the first few months provides a fairly reliable forecast of what kind of adjustment will be made over a longer period of time. The obvious lesson here is that early-appearing indicators, such as loss of appetite, withdrawal from friends and activities, sleep disturbances and escape into alcohol and drugs (including

the hoarding of prescription or over-the-counter elixirs) should be taken seriously. Time alone will not necessarily prove the healer.

Dependency needs frequently come to the fore when the survivor is having great difficulty in coping. Counselors and therapists face the challenge of helping survivors to rekindle their sense of competency and autonomy. This is likely to be a step-by-step progression, in which the therapist may have to play the roles of protector and mentor for some time. The advanced age of the bereaved person does not necessarily stand in the way of therapeutic success. It has been observed in clinical practice and confirmed by research (e.g. Duran *et al.*[9]) that both the individual's personality and his/her social support often make the crucial difference in recovery from bereavement.

It is not unusual to see an elderly person appear relatively unresponsive to a death. In some situations this is the observer's failure to notice subtle but significant changes. But the lack of a strong overt response is sometimes associated with bereavement overload[10]. So much active and re-activated grief from previous bereavements has commanded the person's attention that there is not enough emotional energy available to respond fully to the most recent death. Survivors of the Holocaust and other disasters have often been afflicted in this way.

LATER PHASES OF BEREAVEMENT

Many senior adults have proved highly resilient after experiencing bereavement. Studies do not invariably find that widows sit around weeping and feeling helpless. The gender dimension is important here. Women outnumber men in the upper age echelons and often show themselves more skillful in providing social and emotional support. By contrast, the bereaved older man runs more risk of becoming isolated. In some environments, such as the retirement community with its high density of older women, the widower may be looked after and valued. Nevertheless, there is a major problem of hidden grief among older men, a problem that often persists for years after the loss. Quiet, keeping to himself, expressing little obvious emotion, the older bereaved man is more likely to be suffering intensely than his female peer, with her greater facility in self-expression and more sensitive support network[11]. This not yet well appreciated fact suggests that psychiatrists and other caregivers should explore the possibility of bereavement—even a fairly remote bereavement—as the underlying factor in a variety of behavioral and somatic problems experienced by older men. Unfortunately, some of the most traumatic bereavements leave the elderly survivor with the most limited social support. This is especially the case with suicide[12]. The high rate of suicide among elderly white men each year often leaves their spouses and siblings alone with their grief.

A FEW SPECIAL CONSIDERATIONS

1. Bereavement is a status marker: in spousal death, for example, the survivor is no longer a husband or a wife. From that day forward, society tends to treat him/her in a different way. We can be helpful in supporting survivors' movement to meaningful new roles and the restoration of self-confidence.
2. The "little deaths" that often accompany the later years of life can both anticipate and intensify grief reactions. The old man may have been mourning the loss of his mobility even before his wife died; the old woman who has been relieved of her starring role as a church soloist may have felt abandoned and rejected long before her husband's death.
3. Both elders and young children are sometimes regarded as incapable of grief, although for different reasons. This unfounded assumption results in the additional suffering involved in *disenfranchized grief*[13]. Instead of being a core part of the family communication network and helping to support others in their grief, the elder may be shunted aside, thereby becoming increasingly vulnerable to depression.
3. The death of animal companions can lead to authentic grief reactions[14]. The grief syndrome may be very similar to what is experienced upon the death of a human companion, although the intensity is less likely to endure as long. Rage joins with grief when an elderly person is placed in a nursing home (loss of independence, loss of choice) and then learns that his/her animal companion has been taken to the pound and destroyed.

In a sense, there are no "little griefs", and there may be no "getting over" the greatest losses we experience in our lives. But most elderly adults have learned to live with disappointments, limitations and suffering. When bereavement comes, as a rule they do not need drugs, hospitalization and the whole rigmarole of the health care system. To be offered companionship and to see in that companion's eyes that one is still valued and needed is often all that is needed for the survivor to get on with life.

Suicidal Behaviour

Howard Cattell

Wrexham Maelor Hospital, Wrexham, UK

This chapter concerns itself with completed and attempted suicide in the elderly. It is a major public health problem and the clinician has a crucial influence in determining outcome in suicidal patients. We shall discuss the epidemiological, social, physical and psychiatric factors involved and conclude with a consideration of preventive measures.

EPIDEMIOLOGY

Although there are significant international variations in the official completed suicide rates reported by countries throughout the world, the overall rates continue to remain among the highest in the elderly, as rates increase with age. Males aged 75 and over have the highest rates of suicide in nearly all industrialized countries, with rates for men throughout the elderly lifespan exceeding those for women. However, suicide rates in the elderly, for both sexes, have declined in recent years in many countries, with rates declining by over 30%, for example, in the UK for both sexes between 1982 and 1996[1]. Explanations for such trends are largely speculative.

The prevalence of suicidal thoughts in the elderly has been investigated in some recent studies. Skoog *et al.* examined a population of non-demented 85-year-olds with the finding that among the mentally well, none had seriously considered suicide, but that the presence of mental disorder, especially major depression, was strongly correlated with suicidal feelings[2]. The study by Forsell *et al.*[3] of almost 1000 over-75-year-olds similarly found that those with frequent suicidal thoughts had a strong association with major depression. The conclusion from studies such as these is similar, notably that a careful assessment of the mental state, focused especially on the possibility of depression, is essential before any rational basis for suicidal thoughts be considered.

Little attention has been focused on non-fatal suicidal acts in the elderly, due probably to the phenomenon in recent decades being one of younger people. No countries keep national statistics, but data from centres with well-defined catchment areas allow examination of numbers, rates and trends. Cases of elderly self-harm account for about 5% of the total number of self-harm admissions to general hospitals in the UK and North America.

SOCIAL FACTORS

Studies of individual elderly suicides have drawn attention to a number of social variables. With regard to marital status, widowed, single or divorced individuals seem to be more at risk, with marriage appearing to offer a protective factor. The great majority of elderly suicides occur in a community setting, usually in the person's home. The method of suicide varies over time, with age, gender and other sociocultural factors. It is generally found that men adopt more violent methods than women, e.g. deaths due to hanging and firearms are commoner in men. In the USA, firearms are used by over 60% of all completed suicides, with elderly White men employing this method most frequently.

The role of social isolation as a risk factor has traditionally been considered an important variable[4], although several subsequent studies[5,6] have found no difference between living alone and number of social contacts compared to younger suicides. Bereavement appears as a significant risk factor, with studies of attempted and completed suicide citing its relevance. The first year of widowhood seems to be a vulnerable period, with elderly widowed men being at greater relative risk.

The antecedents in terms of precipitating life events appear to differ in the elderly population compared with younger and middle-aged groups. The latter are associated more closely with interpersonal and relationship problems, financial, legal and occupational difficulties, and less with physical illness, fear of dependency and loss of function, as is often the situation in the elderly. Although complaints of "loneliness" are frequent, a recent Scandinavian study revealed that a similar proportion of younger victims (around 38%) also complained of this difficulty[7].

PSYCHIATRIC ILLNESS

The major finding in the clinical studies of suicide and attempted suicide in the elderly is the presence of psychiatric disorder in the period prior to the event. Among the elderly, however, depressive illness is the most important predictor of suicide and this needs to be emphasized. Most comprehensive studies of completed suicide employing the psychological autopsy method report the prevalence of major depression and other mood disorders to be 60–90%. For example, Conwell *et al.*[8], examining the relationship between age and Axis 1 diagnoses in a sample of 141 completed suicides aged 21–92 years, found 71% and 64% of the 75–92- and 55–77-year-old cohorts, respectively, to exhibit mood disorders, compared with 30% of the 21–34-year-old group. Major depression was diagnosed in almost 60% of the most elderly suicides, with other mood disorders accounting for 10–20% of the sample in this study. The elderly constituted the most homogeneous group, in which non-affective psychoses were rare, addictive disorders less common and late-onset depression the rule.

The symptom profile of elderly suicides prior to the event has been described in earlier studies. Barraclough[4], in examining 30 elderly suicides, reported complaints of insomnia (90%), weight loss (75%), guilt feelings (50%) and hypochondriasis (50%) in the month prior to death. The existence of suicidal ideation often lacks spontaneous expression and it is important that such ideas are explored. Suicidal intent may be less evident, particularly where physical ill-health complaints are prominent. For example, in a recent study from Finland[7] of over 200 elderly suicides, suicidal intent was communicated to attending healthcare professionals in only 18%. The lesson to be learnt is that the presence of somatic symptoms should not detract from a close examination of the mental state with particular regard to a depressive illness and coexistent suicidal thoughts.

Primary substance misuse disorders account for a smaller proportion of suicides than in younger age groups, with prevalence estimates of 5–40%. Similarly, non-affective psychoses are uncommonly reported compared to younger suicides. The association between suicide and dementing illnesses has received limited attention. Although advanced dementia is likely to be a protective factor, the significance of an early dementia as a risk factor for suicide is largely speculative. Individual case studies, however, indicate that in some people the fear of progressive dependency and "institutionalization" is an important dynamic, irrespective of the presence of evident cognitive deficits. There are similarly few reports on the association between personality and suicide in the elderly. Earlier studies described a personality profile of inflexibility, "failure to adjust" and poor adaptation to change. More recently, Duberstein[9] reported a lower openness to experience (OTE) score in elderly compared to younger suicides. This profile may be summarized as a cognitive propensity to perceive problems in dichotomous, black-and-white terms, a rigidly defined self-concept and a diminished behavioural repertoire, thus decreasing the capacity to adapt to loss and change.

BIOLOGICAL FACTORS

Suicide as a distinct neurobiological entity has been investigated in the search to identify potential biological markers, although this research has been almost exclusively undertaken on a younger population. This may be partly attributable to the inherent and often contradictory data on the effect of ageing on central nervous system neurotransmitter systems. Jones *et al.*[10], however, in a study of the suicidal elderly, found significant lower concentrations of cerebrospinal fluid 5-hydroxyindoleacetic acid and homovanillic acid, compared to non-suicidal and normal controls, which is in keeping with other studies in younger suicides.

PHYSICAL ILLNESS

The importance of physical illness as a major antecedent to suicide and attempted suicide in the elderly has long been emphasized. Not only does the older suicide have a higher prevalence of illness compared to his younger counterpart, but the incidence of physical illness greatly exceeds that found in the non-suicidal elderly. Several early studies reported medical illness directly contributing to suicide in around 60–70% of cases, with evidence of higher rates of physical illness among elderly males compared to females. In a recent Scandinavian study[5], the importance of physical ill-health as a life event in the 3 months before death was demonstrated, with elderly men displaying an excess of serious somatic illness compared to elderly females (55% vs. 31%), suggesting gender differences in coping with such age-normative stressors.

Several central nervous system and systemic disorders have been linked with increased risk of suicide. These include epilepsy, multiple sclerosis, Huntington's chorea, head injury, peptic ulcer and rheumatoid arthritis. The association of suicide with cancer is inconsistent with some studies supporting such an association, while others refute the risk, especially among hospitalized patients. In a study from Canada[11] involving 543 elderly suicides, with information obtained from coroners' inquests, those with medical illnesses were significantly less likely to be referred to psychiatric services than those without a medical illness, and those with a terminal illness, comprising almost 9% of the total, were least likely of all to receive a psychiatric assessment. A number of studies have drawn attention to the importance of subjective complaints of pain prior to suicide in the elderly[12,13], with nearly 20% of the samples indicating it to be a major concern prior to death. The point to be reiterated is that the presence of physical illness or presentation with somatic or hypochondriacal concerns may mask the underlying depression, and this type of presentation may be of importance in elderly men, who may be less likely to verbalize their depressed mood or admit to suicidal thoughts.

These findings for completed suicide have their parallel in attempted suicide in the elderly. In a study of 100 elderly suicide attempts, 53% were considered to be suffering from significant physical illness at index assessment following the attempt[14]. The cohort demonstrated an increased mortality from natural causes compared to an age- and gender-matched population and, after an average of 3.5 years, 42% of the original subjects had died.

PREVENTION

Any strategy designed to prevent suicidal behaviour needs to take account of the following factors. Which individuals are likely to be at risk, how are they to be identified, and by whom? To what extent may training and education influence detection and management of vulnerable elderly individuals? How may services be improved to effect a reduction in rates of suicidal behaviour?

Risk Assessment

The act of suicide is a complex phenomenon, involving multiple psychological, physical and social factors operating at a crucial moment in the life of a vulnerable individual, and any risk assessment procedure needs to reflect these varied antecedents. A typical high-risk individual, for example, may be described as an elderly male, living alone following recent bereavement, who may have painful, chronic health problems, who is currently depressed and who has made previous suicide attempts. The problem with applying risk factors lies in the generation of high false-positive predictions associated with the relatively low base rate of completed suicide, and as yet no instruments exist with sufficient sensitivity or specificity to be clinically useful as a risk assessment scale in the elderly. It is the clinical interview that remains the cornerstone of such assessment and needs to clarify key variables. These considerations should not, however, detract the assessor from the real increased susceptibility of the elderly to eventual suicide. This can be seen particularly in elderly attempters, where suicidal intent, as measured by the Beck intent scale, is at its highest for any age group[15]. Attempts in the elderly are also a much stronger predictor of subsequent completed suicide, compared with attempts in younger people, with a ratio of attempts to completion estimated to be around 4:1 compared with between 8:1 and 200:1 for younger attempters. All attempts should be taken seriously.

Recognition

Despite the unique multifactorial precipitants that contribute to individual cases of suicide, opportunities for recognition exist. Suicidal intent, for example, is frequently directly expressed, albeit in different contexts, and should be taken seriously. In the recent study from Finland[2], for example, although nearly half of the victims, men as often as women, had brought up their suicidal ideation or intent to their next of kin, the same intent had only been communicated to healthcare professionals in 18%, despite the great majority (70%) being in contact with health services in the month before their death. The study, however, also reported that in only 24% of the cases had the healthcare professionals even asked about suicidal intentions. It is a misconception to suppose that discussion of suicidal ideas generates attempts. Most individuals feel grateful for a discussion of their suicidal feelings, about which they may feel unduly guilty.

The role of primary care services in suicide prevention is of considerable interest. Most studies report substantial levels of contact: 40–70% of elderly suicides seeing their general practitioner (GP) in the month preceding their death and between 20–50% attending in the preceding week. This raises the important issue of effective intervention at a time when the individual is particularly vulnerable. The importance of training and education programmes for GPs in the recognition and treatment of depression as a means of reducing the suicide rate arises from the Gotland Study[16], in which in the year following training, suicide rates on the island fell significantly compared with other parts of Sweden, and the fall was accounted for largely by the proportion of suicides with major depression. Although not specific to the elderly, such research requires replication.

Research evidence also suggests that a minority of elderly suicides have been in contact with secondary psychiatric services prior to death. Several studies report that around 20% of their series of completed elderly suicides had contact within 6 months and around 10–15% in the preceding 1 month[17,18]. It is important to realize that around 30–60% have no contact with health professionals prior to death, despite the high prevalence of psychiatric disorder.

The issue of treatment adequacy is of significance, given the importance of depressive illness in completed and attempted suicide, with several studies revealing inadequate or inappropriate treatment with psychotropic medication. Conwell[19], for example, described the recognition and treatment of psychiatric symptoms in primary care settings for 51 elderly suicides and found only two who had received adequate treatment, with men and those with coexistent physical illness presenting the greatest challenge. Information from several Coroner's Inquest studies reveal low levels of antidepressant treatment of around 10–25%[11,12,17], although a more optimistic finding has been reported from Sweden, where 50% of a cohort of 75 elderly suicides had a documented history of treatment for affective disorder in the 6 months prior to death[20].

Preventive Strategies

Strategies for the prevention of elderly suicide have been recently reviewed from an international perspective[21]. It would be fair to say that there are limited data on the effectiveness of specific assertive outreach programmes targeting the elderly, although some encouraging initiatives have been described. DeLeo *et al.*[22] described a Tele-Help/Tele-Check service for a population of 12 000 over-65-year-olds in Padua, Italy. The service provides active contacts to clients by trained staff giving information, support and prompt intervention in medical and psychological emergencies. After 4 years of this service, only one suicide was reported, which was significantly lower than expected.

In the USA, the Gatekeepers Program of Spokane, Washington, addresses the need to contact non-self-referrals by training business personnel in the recognition and referral to health professionals of elderly distressed individuals. Such personnel include apartment managers, pharmacists, meter readers, etc. In the UK, the implementation of screening policies for the elderly, the development of community-based old age psychiatry services maintaining close links with primary care facilities, improved education and liaison links with general hospital services, and local and national audit programmes, are likely to be useful.

CONCLUSION

Although there has been a recent decline in elderly suicide rates in several Western countries, the rates remain among the highest for any age group in most societies throughout the world. Despite this, the phenomenon receives little public attention. A common assumption is that suicide in these individuals is an understandable, normal reaction to hopeless, irreversible situations and is consequently unavoidable. There is increasing debate over the individual's "right to die" and self-determination and euthanasia advocates have adopted a more prominent position.

Whatever an individual's personal views are towards the morality of suicidal behaviour, it is incumbent on the physician to pay close attention to the mental and physical state. Available evidence suggests that the great majority of individuals who attempt or commit suicide suffer from both potentially treatable psychiatric conditions (mainly depression) and associated physical and social difficulties for which much can be done. To condemn the elderly by adopting a negative approach is to succumb to the dangers of "ageism".

Genetics and Aetiology

Thomas R. Thompson and William McDonald
Emory University School of Medicine, Atlanta, GA, USA

The literature surrounding the genetics of psychiatric illness and bipolar disorder is expanding, but is limited and often contradictory. Great advances have been made regarding DNA analysis and mapping the human genome. Despite these advances, it is difficult to adequately analyze the available data because the genes studied are complex and exhibit significant heterogeneity in genotype and subsequent phenotype.

There is clear evidence from family studies that bipolar disorder is inherited[1–5]. However, the genetic foundation of this disorder is not well understood. Leonhard's[6] early hypothesis, that bipolar and unipolar illnesses are distinct clinical entities and do not share a common genetic vulnerability, has been supported by empirical data. However, Roglev's[7] recent study supported the polygenic threshold model of transmission, giving credence to the hypothesis that unipolar and bipolar disorder may be one illness. Angst[8] first demonstrated the greater prevalence of both unipolar and bipolar illness in the probands of bipolar patients, compared to unipolar probands who only showed an excess number of unipolar relatives. These data have been replicated in a number of studies[9]. Following up on earlier research demonstrating a linkage between an X chromosome marker (color blindness) and manic depressive illness[10], additional chromosomal studies have linked markers on the X chromosome to bipolar disease and pedigrees from Belgium and Israel[11]. Yet, clearly this mode of genetic transmission could not be solely responsible for bipolar illness. Families with both fathers and sons with the illness are not explained by this mode of transmission, since the father only gives the son the Y chromosome. Other researchers have demonstrated linkage between bipolar disorder and the H-ras-1 locus of chromosome 11 in a pedigree of North American Amish[12,13]. However, separate investigations fail to confirm this linkage in Icelandic, Irish and North American[14] pedigrees. Baron and Egeland later published an update and re-evaluation of their data, essentially reversing their original findings supporting linkage between chromosomes X and 11 with bipolar disorder[15,16]. More recent studies suggest links between bipolar disorder and expanded trinucleotide repeats, potassium channel gene hKCa3, Darier's disease and velo-cardio-facial syndrome[17,18–21]. However, other research can be found that questions some of these links[22–23]. Other chromosomes, including 18, 21, 22, 5, 12 and X, have been implicated in bipolar disorder[17]. The consensus has evolved that the constellation of symptoms making up the phenotypic expression of bipolar disorder are probably due to genetic heterogeneity, and that subtypes within the bipolar spectrum may exist.

The discrepancy in the literature can be best understood using the model of bipolar illness as a genetically heterogeneous disorder. Probably, these are complex genes with variable penetrance that do not exhibit true Mendelian genetics[17]. Because of these factors, it is difficult to obtain significant "power" to demonstrate gene linkage, explaining some of the conflicting results found in the literature[24].

In the elderly, bipolar disorder can be divided into those patients with an early onset of their manic symptoms and those patients for whom symptoms first appear in late life, thereby underscoring possible genetic etiology vs. environmental factors contributing to the expression of manic symptoms. Mania in geriatric patients may be due to bipolar disorder, with early onset and later recurrence or chronic course, or to the first episode of mania occurring in late life. In Shulman and Post's[25] review of bipolar patients admitted to the hospital after age 60, the mean age of onset of the manic symptoms is 60 years. Similarly, in a group of manic hospitalized patients over 65 years old, Stone[26] found that 26% had no prior history of affective disorders. Other larger epidemiologic studies with patient populations of all ages have demonstrated that the onset of bipolar disorder peaks at an early age and declines throughout an individual's lifetime[27–30].

Older adults presenting with the same phenotype (i.e. manic symptoms) may therefore have a very different past clinical course of their illness and may possibly fit into different subtypes of bipolar disorder (e.g. early and late onset).

Stone's[26] review of elderly patients with mania demonstrates that patients with a family history of affective disorder have an earlier average age of onset of their manic symptoms (53 years, compared to 60 years for patients with no family history of affective disorder). Further studies have also supported the notion that patients with early-onset mania (usually defined as less than 30 years old) have an increased number of relatives with affective disorder and possibly an increased genetic loading for bipolar disorder[31–33]. However, other authors have not found a relationship between age of onset of manic symptoms and family history[28,34].

There is also evidence that females are more likely to develop early-onset mania[28,35]. This evidence would provide support for the notion that genetic loading and the X chromosome may play a significant role in early-onset mania. As Winokur[28] points out, other studies indicate that women are more common than men in both the early- and late-onset groups[36–38]. However, recent epidemiological studies in the USA show approximately equal risk of bipolar disorder in males and females[39]. Additionally, Spicer notes an increase in first episodes of mania among men but not women over 60[40].

Clinical studies would also suggest that late-onset mania is more often precipitated by organic factors than mania, which has its onset early in life[41]. Krauthammer and Klerman[42] were the first to review causes of secondary mania (mania directly related to

organic illness, rather than an idiopathic cause). These researchers describe manic symptoms that were secondary to drugs, infection, neoplasia, epilepsy and metabolic disturbances. The patients in their study had a later onset of symptoms (average age of onset 41 years) and fewer family members with affective illness than is commonly reported in the literature describing bipolar subjects.

Stasiek and Zetin[43] have updated Krauthammer and Klerman's original study with additional organic causes of manic symptoms. These authors again emphasize the importance of looking for an organic cause of mania when there is a negative family history for affective disorder or a later onset to the bipolar disorder. Neurological disease, particularly cerebrovascular disease, is also associated with secondary late-life mania[44–46]. Neuroimaging of manic geriatric patients has shown differences in the basal ganglia morphology and the putamen volume when compared to control subjects[47,48].

McDonald *et al*. demonstrate a correlation between bipolar disorder and subcortical hyperintensities, as evidenced on magnetic resonance images in patients with the onset of manic symptoms after the age of 50 years[49,50]. Only two of the 10 patients in this study had a family history of affective disorders[49]. The significance of subcortical hyperintensities has been debated, although they are thought to result from a focal loss of brain parenchyma, due to ischemia from any cause including hypertension, vasculopathy, atherosclerosis or thromboembolism[51].

Finally, Yassa *et al*.[52] find a low incidence of organic factors precipitating mania in an elderly population. However, seven of their 10 geriatric bipolar patients demonstrated a stressful event in the 6 month period prior to their manic episode. None of these patients had a family history of affective disorders.

AFFECTIVE DISORDERS

In summary, there is evidence from family studies and chromosomal linkage studies that manic depressive illness is transmitted genetically and may have more than one mode of genetic transmission. There is also evidence from clinical studies that there may be a different etiology for bipolar disorder, which has an onset early in life, compared to those which begin in older adults. Late-onset mania is more often associated with organic precipitants and, as in other types of mania, may be closely associated with stressful events. Patients with an earlier onset to their symptoms more often have a family history of affective disorder. Clinically, patients who present with manic symptoms after the age of 50 years should be given careful consideration for an organic cause to their symptoms, particularly if there is no evidence of affective disorders in other family members.

Epidemiology and Risk Factors

S. Lehmann and P. Rabins

Johns Hopkins Medical Institutions, Baltimore, MD, USA

In recent years there has been renewed research and clinical interest in the syndrome of mania in the elderly. Much of the current work in this area has been focused on the following issues: can mania first present in late life?; do the causes, features, clinical course, and responsiveness to treatment differ in older manic patients compared to younger persons with mania?; how do elderly manic patients with an early age of onset of illness differ from those with onset of illness in late life?

EPIDEMIOLOGY

The manic phase of bipolar affective disorder, or mania, is an uncommon disorder in the elderly. In the five-site Epidemiologic Catchment Center study of more than 20 000 non-institutionalized individuals, 1 month prevalence rates for mania were 0.4–0.8% for 18–44-year-olds and 0.2% in the 45–64-year-old group. Notably, no cases of mania were identified among people over age 64[1].

Nevertheless, elderly patients with mania are seen in significant numbers in a variety of clinical settings. In Roth's[2] retrospective review of 464 psychogeriatric patients over age 60 in a long-term hospital, 14 cases were manic. This represented 6% of the total number of cases of affective disorder. Two studies of first admissions to British psychiatric hospitals, using Department of Health statistics, found that the number of first admissions with mania either remained steady with age[3] or increased with advancing age[4]. In the USA, other studies in short-stay hospitals have reported that mania accounted for approximately 5% of elderly psychiatric admissions[5,6]. Similarly, one recent study identified 39 patients over age 60 with bipolar, manic or mixed state disorder out of 791 inpatient admissions (approximately 5%) over a 4 year period[7]. Most studies of elderly manic patients have found more females than males[5–8] but one recent report found a slight male preponderance[9].

For the majority of elderly bipolar patients, the first episode of affective disorder is usually a depression. Indeed, it is quite common for a first manic episode to occur 10 years or more after an initial depressive episode and to be preceded by multiple depressive episodes over many years[5,10,11]. Generally, elderly patients have been found to have suffered more episodes of depression before a first manic episode and to have had a long gap between an initial depression and a first manic episode than young manic patients[11].

It must be noted that, at the present time, there is no agreed-upon standard regarding which age should serve as the dividing line between early and late onset of bipolar illness. Furthermore, age of onset itself is often difficult to determine with exactitude. Different criteria have been used among various investigators to identify age of onset, including first onset of symptoms, first hospitalization and first time at which the patient met full criteria for the disorder[7]. Several recent studies have observed bi-modality in age of onset of mania among elderly patients. In these studies, one subgroup of patients was found to have developed bipolar disorder in early life with a mean age in their 30s, and another subgroup developed a first manic episode after age 60[7,11]. Late-onset bipolar patients tend to have had a longer gap between first depression and first mania than early-onset bipolar patients[11], and in one study were more likely to be married or living with a significant other[7].

RISK FACTORS

A number of studies have reported that elderly bipolar patients who had an early age of onset were more likely to have had first degree relatives with affective disorder than late-onset elderly bipolar patients[11,12]. This trend holds across studies that have used ages between 20 and 60 years to divide early and late cases and suggests that genetics plays a greater role in the disease of early-onset bipolar disorder. At the same time many investigators have reported associations between late-onset mania and cerebrovascular and neurologic disease. A cohort study comparing 50 elderly patients with mania to 50 age- and sex-matched patients with unipolar depression found that 36% of the manic patients had neurological disorders compared with only 8% of the depressed patients[13]. Interestingly, among these neurologically impaired manic patients, 33% had a positive family history of affective disorder in first-degree relatives. In another recent study comparing elderly patients with early- and late-onset bipolar disorder, researchers found that patients with late-onset illness were more likely to demonstrate cerebrovascular risk factors or clinical evidence of cerebrovascular disorders[7]. In a prospective study of mania in 35 patients over age 60, the elderly manic patients had more cortical atrophy on CT scans than age-matched controls[11]. However, no significant difference in cortical atrophy was found between elderly patients with early- and late-onset mania. In addition, subcortical hyperintensities have been reported on magnetic resonance imaging (MRI) in elderly patients with mania[14]. These hyperintensities are believed to be due to focal loss of brain parenchyma but they do not seem to be specific to elderly patients with mania, since subcortical hyperintensities have also been found in late-onset depression as well as late-onset paranoid disorders[15].

Krauthammer and Klerman[16] proposed criteria for secondary mania, which included cases of no prior family history, no prior

psychiatric history, and a definable medical or neurological etiology. While it is true that organic factors may precipitate mania in some elderly patients, these cases appear to be in the minority. Manic episodes can be caused by such widely prescribed medications as levodopa, procyclidine, pergolide, selegiline and bromocriptine[17]. A variety of steroids have been reported to produce manic syndromes, as have thyroid supplements, and there have been case reports of mania associated with H2-antagonists, antiarrhythmics, estrogen and antitubercular agents[18]. In addition, mania can occur in association with systemic infections, such as influenza, Q fever and St Louis type A encephalitis. Cases of mania secondary to space-occupying lesions, such as meningiomas, subarachnoid hemorrhages and metastases (usually in the non-dominant hemisphere), have also been reported[6]. In these cases, mania usually resolves with removal of the offending pharmacologic agent or treatment of the underlying disorder.

More commonly, mania has been reported in elderly patients with cerebrovascular and neurological disorders. One prospective study found that 20% of patients with mania over the age of 60 had a first manic episode closely temporally related to a cerebral organic disorder[11]. Another prospective study of 20 manic patients with onset over age 50 found that 65% developed bipolar disorder after a silent cerebral infarction[19]. In particular, injury to the right hemisphere appears to be strongly associated with the development of mania. There have been reports of secondary mania in patients with ischemic injury to right-sided basal ganglia, orbitofrontal cortex, and right basotemporal cortex[20]. It has been hypothesized that these brain areas may be significant because of their connections to the limbic system and the modulation of emotion. Overall, however, mania following stroke is much less common than depression after a stroke. In one large study of 700 stroke victims only three developed manic syndromes[21]. There have been two case reports of mania secondary to infarctions in the thalamic and perithalamic areas[22]. Starkstein *et al.*[23] studied 11 patients who developed mania after stroke and found that eight had lesions involving limbic areas and nine had right hemispheric involvement. These patients also had significantly larger bifrontal and third ventricular brain ratios than matched control patients, indicating pre-existing anterior subcortical atrophy. Moreover, almost half of the patients had a family history of affective disorder in a first-degree relative. Taken together, the current literature on mania in patients with neurologic and cerebrovascular disorders underscores that genetic loading is also a factor contributing to the development of mania in these patients as well. Furthermore, while up to a quarter of elderly manic patients in various studies have been found to have some evidence of concurrent cerebral disease, it is still unclear to what extent these impairments play an etiological role in the development of mania. If cases in which subjects with a known previous history of affective disorder are excluded, few cases of clear secondary mania are found[6,11,12]. An exception to this is Shulman *et al.*[13], who felt that 36% of elderly patients they studied who were hospitalized with mania had true secondary mania associated temporally with clearly documented neurological disorders.

Mania can occur in the setting of dementia. In a chart review of 134 patients with Alzheimer's disease, 2% were found to have had mania[24], although others have reported higher rates[25]. Broadhead and Jacoby[11] found that 32% of elderly manic patients studied scored in the demented range on cognitive testing, even though they had no history of progressive cognitive decline. Furthermore, more extensive cortical atrophy on head CT correlated with poorer test scores, but there was no significant difference between early- and late-onset manic patients with respect to CT findings or cognitive changes. It is unknown at this time whether these patients have progressed to develop true dementia. In one retrospective study of 92 elderly patients with mania, only three went on to develop documented dementia over a 10 year follow-up period[12]. To date, there does not appear to be an increased risk for elderly manic patients to develop dementia compared to the rest of the population.

As in younger patients, stressful life events have been felt by some investigators to precipitate mania in elderly patients. One study that reported on 10 elderly manic patients found that 70% had major changes in lifestyle in the 6 months preceding onset of mania. Stresses included marital discord and disruption of living arrangements[5].

Mania: Clinical Features and Management

S. Lehmann and P. Rabins

Johns Hopkins Medical Institutions, Baltimore, MD, USA

Descriptions of manic syndromes in elderly patients published during the 1960s and 1970s tended to emphasize differences in clinical features compared to younger manic patients. Post felt that elderly manic patients had more depressive features and more mood-incongruent persecutory delusions, but were less likely to have flight of ideas[1]. Slater and Roth noted that euphoric states in older manic patients tended to be less "infectious" and had more expressed "hostility and resentment"[2].

More recent retrospective and prospective studies, on the other hand, suggest that symptoms are actually quite similar across the age span. For example, two studies have reported that hyperactivity, insomnia and thought disorder (e.g. flight of ideas) occur in 60% of elderly manic patients. Other common manic symptoms include grandiose delusions, irritability, hypersexuality and paranoid delusions[3,4]. Similarly, a more recent study of 14 patients over age 65 hospitalized with a first manic episode found that 43% had psychotic features, including grandiose and persecutory delusions[5]. In a prospective study comparing hospitalized manic patients over age 60 to those under age 40, no differences were found between young and old patients in the time course or outcome of the manic episode. However, the authors had the clinical impression that younger patients tended to experience a more severe illness than older patients. The authors also noted that more elderly patients relapsed into a depressive episode after discharge from the hospital[6].

There has been little research to date comparing elderly manic patients with early- and late-onset bipolar disorder in terms of clinical presentation, response to treatment or clinical course. One intriguing study of patients over age 60 hospitalized with bipolar, manic, mixed or depressed states found that elderly patients with late-onset bipolar disorder were more likely to have psychotic features compared to patients with early-onset bipolar disorder. However, early- and late-onset bipolar patients did not differ in terms of pharmacological treatment, hospital stay length, or likelihood to be admitted for a manic, mixed-state or depressed episode[7].

Although several authors have noted that cognitive dysfunction is common in elderly patients with mania, the relationship between mania and dementia in older patients remains complex. Broadhead and Jacoby[6] found that 32% of elderly manic patients scored within the demented range on a cognitive assessment, even though none of the patients had a history of progressive intellectual decline. Moreover, there was no significant difference between manic patients with early- and late-onset bipolar disorder in terms of cognitive impairment. In a 5–7 year follow-up study of 25 elderly patients previously hospitalized for acute mania, 32% had developed a clinically significant cognitive disorder[8]. In contrast, an earlier 10 year follow-up study of 92 elderly patients with mania found that only 3% had developed dementia[9]. Clearly this is an area that warrants further study.

TREATMENT AND MANAGEMENT

A recent study of mental health service use by elderly patients with bipolar disorder and unipolar major depression found that the bipolar patients used more case-management services, were three times more likely to use partial hospitalization and three times more likely to have had at least one psychiatric hospitalization over the 6 months prior to the assessment[10]. This study highlights the importance of effective treatment and mental health monitoring for elderly patients with bipolar disorder.

As with younger patients, lithium carbonate is the mainstay of pharmacological treatment in the older manic patient. There are clear changes in the pharmacokinetics of lithium with age, due to age-related decline in creatinine clearance. In people with no renal disease there is a 30–50% decline in glomerular filtration rate (GFR) between the third and eighth decades. Since lithium is almost exclusively excreted through the kidneys, this leads to decreased clearance of lithium with age. As a result, the biological half-life in the serum increases from 18 h in adolescents to 36 h in people over age 60 and may be even longer in elderly patients with renal disease[11].

In addition, there is considerable agreement that both the toxic and therapeutic effects of lithium occur at lower plasma levels in the elderly compared to younger patients. Plasma levels of lithium that would be considered therapeutic for a young manic patient cause delirium in some elderly patients. The reasons behind this are unclear but it has been hypothesized that this phenomenon reflects an increase in brain sensitivity to lithium. Fine hand tremor secondary to lithium also seems to occur more frequently in people over age 60 than in younger patients. In summary, therefore, it is prudent to begin elderly manic patients on lower doses of lithium than one would for younger patients, and to aim for lower plasma levels of 0.5–0.6 mmol/l, even in the acute phase of treatment. For long-term maintenance and prophylaxis, even lower plasma levels of lithium of 0.4–0.5 mmol/l are often effective for this older age group.

Studies of patients taking lithium over many years indicate that lithium rarely causes changes in glomerular filtration rate or renal failure[12]. Furthermore, lithium does not appear to decline in efficacy over the lifespan[13]. However, for a variety of reasons, some patients become unable to tolerate lithium as they age. In these cases lithium treatment must be replaced or supplemented by other mood-stabilizing medications. As with younger patients, anticonvulsants such as carbamazepine,

valproate and clonazepam are being used more frequently as an alternative or adjunct to lithium treatment[14]. Although systematic data regarding the efficacy and toxicity of carbamazepine treatment in elderly manic patients are lacking, there are a few reports indicating that it can be safe and effective in older patients[15]. The major risk of carbamazepine is the rare occurrence of aplastic anemia or agranulocytosis[11]. However, many older patients have difficulty tolerating this medication, due to its propensity to cause sedation and ataxia.

In recent years valproate has been widely prescribed for the acute treatment of mania in both young and elderly patients with bipolar disorder. A case series study of seven older patients with long-standing bipolar disorder who had failed to respond to conventional medications reported at least minimal improvement in six out of seven patients after valproate was added adjunctively to the medication regimen[16]. Two retrospective studies of valproate treatment of patients over age 60 hospitalized with mania found valproate effective in improving symptoms of mania at serum levels of 31–106 μg/ml[17,18]. In another retrospective study assessing the efficacy of lithium compared to valproate in patients over age 55 hospitalized for mania, 38% of elderly patients receiving valproate were improved at discharge compared to 67% of patients receiving lithium. However, the authors note that fewer patients on valproate therapy were within the therapeutic range and valproate serum levels of 65–90 μg/ml correlated with a better therapeutic response than did lower serum levels[19].

Gabapentin is a new anticonvulsant with gaba-ergic and glutaminergic properties that has been shown to have antimanic effects and may be effective as an adjunctive agent in the treatment of mania[20]. It has not yet been studied systematically in elderly patients. Similarly, in a mixed-age population of patients with acute mania, olanzapine, a novel neuroleptic, was found to be more effective than placebo[21]. Novel neuroleptics such as risperidone and olanzapine have the potential to be particularly useful adjuncts in the treatment of mania in the elderly because of their lower rates of extrapyramidal side effects and tardive dyskinesia, compared with traditional neuroleptics[22]. As a result, they may be better tolerated by elderly manic patients than traditional neuroleptics, such as haldol, for adjunctive treatment of psychosis and agitation. More research is needed on both the short- and long-term effects of these newer mood-stabilizing and antipsychotic medications in older persons.

Finally, the clinical management of older patients with mania must always include attention to psychosocial support issues and psychotherapy. As with younger patients, individual counseling, emotional support and illness education are critical to a successful outcome. Additionally, involvement of family members and significant others in the acute treatment and long-term management of the illness helps to ensure compliance with treatment recommendations and early detection of signs of relapse.

In a follow-up study of approximately 400 bipolar patients, Grof *et al.*[1] found that virtually every patient experienced recurrence of the illness. The course of the recurring episode was predicted by the course of the previous episode. The first recurrence usually occurs 40–48 months after the initial episode, but later in the course of the illness, there may be more frequent relapses and the interval between episodes may shorten up to 50%.

Winokur[2], using IOWA-500 data from a long-term follow-up study, suggested that bipolar illness may burn itself out with time; thus, aging may be a mitigating factor. Cutler and Post[3], however, in a review of a small number of untreated patients with severe and prolonged bipolar disorder, found a tendency for more rapid recurrences late in the history of the illness with decreasing periods of normality. In other words, if bipolar illness emerges in later years, then the episodes of mania or mania mixed with depression may tend to cluster with each other.

The course of the illness also depends on the age of onset. Mania, in general, is an illness of early onset. The mean age of onset is 30 years with a range from teens through 50 years. However, there are several patients who experience their first episode of manic illness in the later years of life[4–7]. Unfortunately, the prognosis of mania in the elderly has not been studied as systematically as in the younger population.

Post[8,9] suggested that the first onset of affective illness in late life carried a less favorable prognosis than early-onset patients. He further stated that elderly manic patients tend to remain disturbed somewhat longer. Although most episodes may subside in a few weeks, some may last up to 6 months. In the elderly, recurrent episodes of mania tend to occur more frequently, most commonly every 1 to 2 years, as compared to longer intervals between episodes in younger patients. Post also noted that late-onset patients displayed a significantly less frequent family history of affective disorder compared to early-onset patients.

In another retrospective study of 67 elderly bipolar patients, Shulman and Post[10] found that the first manic episode occurred at about 60 years of age, often after a latency period of 10 years from the first affective symptoms. There was an average of three depressive episodes before the occurrence of the first manic episode in these patients.

More recently, Kit Stone[11], in a retrospective study of 92 patients admitted with mania over the age of 65, reported that 26% had no prior history of mood disorder, 30% had previously only experienced depression, half of them had at least three episodes of depression before the onset of mania and the mean latency period for the first depressive symptoms to the onset of first manic episode was 16 years. He also noted that patients with a family history of affective disorders had a significantly earlier age of onset.

In a prospective, comparative study of 35 elderly manic patients over the age of 60 and 35 young patients below the age of 40, Broadhead and Jacoby[12] reported that elderly manic patients suffered more depression before the first manic episode and had a longer interval between the first depression and the first manic episode than the young bipolar patients. They also reported clinical differences between the young and the old manic patients; although the young experienced more severe illness than the old, the elderly patients appeared to have a more fragile recovery and were more likely to relapse into a depressive episode during resolution of their manic illness. Within the elderly group, 50% of the early-onset subgroup had a family history of affective disorder in first-degree relatives as compared to only 14% in the late-onset subgroup.

In a study describing the relationship between age, signs and symptoms of mania in 40 inpatients, Young and Falk[13] reported that increasing age is associated with attenuated manic response characterized by less intense level of over-activity and sexual drive, while thought processes are generally less disrupted. They also noted greater residual psychopathology in elderly patients as compared to younger patients over a period of time. These findings are similar to previous follow-up studies by McDonald[14], Wertham[15] and Lundquist[16], who found that duration or chronicity of manic illness increases with age.

Ameblas[17] reported a special relationship between life events and the onset of the first manic episode. This finding suggests that later in life, less stressful events may precipitate mania, and therefore late-onset manic episodes may be related to increased cerebral vulnerability in the elderly.

There has been a recent interest in the concept of secondary mania. Krauthammer and Klerman[18] described secondary manias in heterogeneous groups of illnesses, including metabolic disturbance, drugs, infections, neoplasms and epilepsy. There is also increasing evidence that elderly patients with coarse brain changes secondary to stroke, head trauma and other neurological conditions appear to be more vulnerable to mania. Elderly subjects are more prone to develop these conditions and the prognosis of these secondary manias depends in part on the prognosis of the conditions causing such manic episodes.

Spicer[19], in an attempt to explain the increased incidence of mania with old age (a finding not replicated in most studies), suggested that manic episodes might occur on the basis of dementia. Shulman and Post[20], Stone[11] and Broadhead and Jacoby[12], however, did not find an association between mania and dementia in elderly patients. In a retrospective clinical study of mania and old age, Shulman and Post[12] did find a temporal association between onset of mania and history of cerebral disease in 16 out of 67 (24%) of their patients. Glasser and Rabins[21]

suggested from their study that elderly men with coarse brain changes as a result of stroke, head trauma and other neurological conditions, appear to be most vulnerable to developing mania. Kit Stone[11] reported that 24% of his elderly patients developed mania following some sort of cerebral insult. In their comparative study of young and old manic patients, Broadhead and Jacoby[12] found that 20% of their elderly patients had first manic episodes that were closely related temporally to cerebral organic disease, in contrast to none in the younger manic group. In other words, manic episodes in late life may derive not only from a predisposition to bipolar disorder but also from cerebral pathological changes, and therefore the prognosis of the brain disease may determine the prognosis of mania in these patients.

Shukla *et al.*[22] studied 20 patients with mania after head injury. They suggest a significant relationship between post-traumatic seizures and development of mania. Elderly individuals are more prone to falls and subsequently at a higher risk for developing mania after head injuries. In a recent magnetic resonance imaging (MRI) study of elderly manic patients, McDonald and Blazer[23] found an increased incidence of sub-cortical hyperintensities in the right middle third of the brain parenchyma.

Young and Falk[13] noted a less vigorous response to lithium in older than in younger manic patients. This difference, based on age, was even more impressive since their sample maximum age was 66 with a mean of 36 years. Their data suggest that increased age may be associated with attenuation of aspects of manic psychopathology and response to pharmacotherapy. Himmeloch *et al.*[24], in a study of 81 bipolar patients over the age of 55, demonstrated that neurological status rather than age is the critical factor determining the natural course of the illness. Neurological status not only determined the evolution of chronic mania; it also predicted poor treatment response and lithium-induced neurotoxicity.

Despite the possible difference in the clinical presentation and response to treatments of mania in young and old age, evidence indicates a good therapeutic response to lithium for both an acute manic episode and prophylaxis in elderly patients, but close monitoring is required, with particular attention to interactions with other illness and medications. Contrary to the general belief, the prognosis of mania in old age is good and comparable to that of the young manic patient.

The Management of Acute Mania

John L. Beyer and K. Ranga R. Krishnan

Duke University Medical Center, Durham, NC, USA

Primary acute mania in the elderly (>65 years) is rare, its prevalence being much less than 1%[1]. Kramer *et al.*[2] reported that no patients with mania were identified out of 923 elderly persons interviewed in the Epidemiologic Catchment Area study. However, other researchers[3] have reported that 5%–10% of elderly patients presenting with mood disorders have mania or hypomania. Further, approximately 4%–5% of geriatric patients hospitalized for acute conditions in a state psychiatric facility were noted to have bipolar disorders[4]. Most elderly bipolar patients appear to be individuals who had an early onset of bipolar disorder and now have reached an older age. However, a first episode of mania in late life is not unknown and appears to be more commonly associated with underlying neurological/medical illnesses[5] and the absence of family history of affective disorders[6].

Clinicians who treat the elderly are aware that late-life mania presents unique treatment challenges. Older patients with mania who require hospitalization tend to have a slower course of improvement than younger patients[7]. This often results in longer hospitalizations and the appearance of increased treatment resistance. Further, rates of cognitive and functional impairment were found to be much higher in elderly bipolar patients over a 5 year period than seen in the general population[8].

Complicating treatment guidelines is the observation that, as opposed to bipolar disorder in younger populations, the treatment of bipolar disorders in the elderly remains an understudied area[9]. The treatment of late-life bipolar disorder is primarily extrapolated from data obtained in studies of younger patients or mixed patient populations, uncontrolled studies of elderly patients and case reports.

TREATMENT GOALS

Management of acute mania initially begins with the treatment of the acute symptoms and assessment of cause. This can be done either in the hospital or in an outpatient setting. However, since the manic patient frequently presents with excessive energy, irritability, grandiosity, impulsiveness or even psychosis, the physician must first determine the appropriate level of care required for treatment. Usually, hospitalization is required when patients present with severe symptoms or psychosis which affects functioning and requires behavior management. This may be especially true for the patient with cognitive impairment. Hospitalization can often be useful in facilitating the evaluation of first episodes and increasing both acute and long-term medical compliance. Elderly patients in nursing care facilities may be able to be treated without hospitalization if the support system is sufficient. A hypomanic patient can usually be treated as an outpatient as long as he/she demonstrates adequate compliance and the primary caregiver does not feel overwhelmed.

Before a primary manic episode is diagnosed, a potential medical or substance-induced etiology must be ruled out. Therefore, comprehensive evaluation, physical work-up and diagnosis are necessary prior to treatment of mania in the older person. After stabilizaton, the focus of treatment is then directed to the maintenance phase, relapse prevention and other necessary social interventions.

PRIMARY MEDICATIONS FOR ACUTE MANIA

Lithium

Efficacy

As in younger patients, lithium is indicated in elderly manic patients for both treatment of acute manic episodes and prophylactic maintenance. Although it has been suggested that lithium may not be as effective in older patients, most studies have demonstrated that lithium is equally effective in elderly patients. However, lithium does require special precautions for use in the general adult population and especially the geriatric population. In fact, underlying dementia, cardiovascular disease or kidney disease in the elderly can increase the potential for neurotoxicity, cardiotoxicity and nephrotoxicity[10,11]. Lithium is not considered an ideal choice for patients with these problems, despite their positive response to the drug.

Treatment Considerations

Prior to starting patients on lithium, the patient's medical history should be reviewed with special attention to systems that may be affected by lithium. Laboratory tests should include a complete blood count (CBC), serum chemistry panel [with plasma sodium, potassium, blood urea nitrogen (BUN) and creatinine levels] thyroid function tests [iodothyronine (T3), thyroxine (T4), and thyrotropin-stimulating hormone (TSH) levels] and an electrocardiogram (ECG). If the elderly patient is suspected of having renal dysfunction, a 24-hour urine collection measuring creatinine clearance is the best way of assessing glomerular filtration rate (GFR). However, if this is not feasible, a less precise estimate of GFR and renal clearance can be calculated by measurements of BUN and creatinine. Unfortunately, in patients with low muscle mass, the values may be overestimated. An electroencephalogram (EEG), computed tomography (CT) head scan or magnetic resonance image (MRI) of the brain are unnecessary unless specific neurological deficits are found in these patients on physical examination.

Principles and Practice of Geriatric Psychiatry, 2nd edn. Edited by J. R. M. Copeland, M. T. Abou-Saleh and D. G. Blazer

Dose

Older patients may be started on low doses of 150–300 mg/day, usually divided into two doses. The dose should be gradually increased according to the patient's response and ability to tolerate side effects. Lithium pharmacokinetics are affected by the aging process. As one ages, there is a decrease in total body water, renal blood flow and glomerular surface area. Therefore, the excretion of lithium decreases with age. This tendency is parallel to the reduction in creatinine clearance with age. Several studies have shown that elderly patients require one-third to one-half the lithium dose suitable for young adults[12]. A longer elimination half-life (<36 h) seen in the elderly suggests that a steady state may be reached within 7–10 days of initiation of therapy. Initially, lithium levels should be monitored at least once a week, with the blood level estimated at least 12 h after the last dose (the most convenient time would be early morning prior to the first dosage).

The target for lithium concentration level should always be based on individual therapeutic response. However, studies have indicated that lithium levels of 0.8–1.2 mEq/l are generally recommended. Those studies have predominately been done on mixed-age populations. Some researchers have suggested that the elderly may respond to relatively lower serum lithium levels (0.3–0.5 mEq/l)[13].

Side Effects

General Side Effects. Common side effects with lithium therapy are a benign fine tremor, metallic taste, polyuria, polydipsia, gastric irritability, nausea, weight gain and mild sedation. The presence of tremor is an especially common and bothersome side effect in all adults taking lithium, but it tends to increase with age[14]. The tremor occurs at relatively low serum concentrations, and may worsen as the concentration increases[9]. Various researchers have found the incidence of tremor in the elderly to be between 17.5–58%[15–17].

Lowering the dosage may reduce most of these side effects. Taking the lithium with food or using the enteric coated form can reduce the problem of gastric irritation. If lithium tremor is persistent, propranolol may be helpful, although its use should be closely monitored because of the potential for other side effects to which elderly patients may be susceptible. Low-dose thiazide diuretics may improve polyuria and polydipsia, but should be used with caution (see below).

Signs of lithium toxicity include the significant exacerbation of the above symptoms, as well as vomiting, diarrhea, ataxia, slurred speech, severe lethargy, weakness, blurred vision, severe drowsiness or, at times, agitation. Lithium toxicity is often seen in the acute treatment of a manic episode in an older adult as the lithium dose is being regulated. Therefore, frequent monitoring of blood levels and side effects is essential. If symptoms are present, lithium should be stopped immediately. Dialysis may be used to remove excessively high levels of lithium from the blood. Recovery from lithium toxicity may be prolonged in the elderly due to slow renal clearance, the presence of an underlying dementia, or possibly subclinical brain changes[18].

Neurotoxicity. Excessive amounts of lithium may result in neurotoxic effects, characterized by confusion, disorientation, memory loss, ataxia and akathisia. However, several reports have shown that neurotoxic effects may develop at relatively low serum concentrations of lithium in the elderly. Himmelhoch *et al.*[10] found that the presence of an underlying neurological disorder that produces parkinsonian symptoms, dementia or episodic confusion is highly predictive of lithium-induced neurotoxicity, even with low serum lithium concentrations.

Cardiovascular Toxicity. Lithium may cause both non-specific and specific ECG changes associated with repolarization. Some of the specific ECG changes are T-wave flattening or inversion (which may be caused by potassium depletion) and the appearance of U waves. Adverse effects of cardiotoxicity can present as conduction defects, irregular and slowed sinus rhythm, first degree atrioventricular (AV) block, or premature ventricular complexes (PVCS). Ventricular tachycardia is a sign of severe cardiotoxicity. Older patients are at a higher risk for these cardiovascular effects, even with milder degrees of lithium toxicity. Regular comparison of the ECG with baseline measures is important once the patient starts treatment with lithium.

Nephrogenic Diabetes Insipidus. Lithium may also cause symptoms of nephrogenic diabetes insipidus in up to 20–40% of patients on maintenance lithium therapy[19]. This condition is caused by the inability of the patient to concentrate his/her urine. The result is the excretion of large quantities (>3 l/day) of urine, which can cause dehydration if comparable fluid intake is not maintained. This syndrome is usually reversible and is not dose-related[20]; however, there appears to be a risk of persistent concentrating defects even after the lithium is stopped[21,22]. Diabetes insipidus can be treated effectively with amiloride or hydrochlorothiazide (HCTZ), but each of these also has the possibility of causing electrolyte imbalance, particularly in geriatric patients.

Thyroid Abnormalities. Lithium therapy can interfere with thyroid functioning, such as synthesis, degradation and release of T3 and T4. Decrease in thyroid hormone can stimulate TSH by negative feedback. Even though compensation may occur initially, some patients develop signs of hypothyroidism[23] with goiter. If detected early, hypothyroidism is reversible, either by stopping the lithium or by the use of thyroid supplements. Lithium should be discontinued if the patient develops goiter, as this can be reversed if detected sufficiently early.

Drug Interactions

Lithium is eliminated from the body through the kidneys. Therefore any medication which may alter kidney function (especially glomerular filtration or electrolyte balance) will change lithium concentration. Medications frequently prescribed to elderly patients that may have significant drug interactions with lithium include anti-hypertensive medications [thiazide diuretics, loop diuretics, angiotensin-converting enzyme (ACE) inhibitors, and calcium antagonists], non-steroidal anti-inflammatory drugs (NSAIDs), carbamazepine, theophylline, caffeine and aciclovir. Selective serotonin-reuptake inhibitors (SSRIs) have been noted to increase the risk of lithium toxicity when used in conjunction with tricyclic antidepressants (Salama, Noveske, Vesely). Aspirin (acetylsalicylic acid) has not been shown to affect lithium concentrations.

Carbamazepine (CBZ)

Efficacy

Carbamazepine, a tricyclic anticonvulsant drug, has proven efficacy in treating adults with acute mania[24–28]. However, all of these studies were done in mixed age adult populations. Systematic studies of carbamazepine in the elderly are lacking. Although lithium remains the preferred treatment for patients with the classic presentation of bipolar disorder, the response rate

drops to 50% when the full bipolar spectrum is considered[29]. Greil *et al.*[30,31] have found that carbamazepine may be useful in patients with non-classical features (mixed or rapid cycling bipolar disorder) or subgroups with depressive or schizophrenia-like features. A few investigators have identified increased benefit with carbamazepine when they treated patients who had EEG abnormalities associated with symptoms of rage and violent behavior[32].

Treatment Considerations

Prior to starting patients on carbamazepine, the patient's medical history should be reviewed, with special attention to previous episodes of blood dyscrasias or liver disease. Laboratory tests should include a complete blood count (CBC), serum chemistry panel, and liver function tests [lactate dehydrogenase (LDH), ALT, AST, bilirubin and alkaline phosphatase levels].

Dose and Administration

Treatment in older patients should be initiated with low doses, starting with 200–400 mg/day by mouth. The dose should be increased gradually and slowly. Carbamazepine therapeutic levels are in the range 4–12 ng/ml; however, these parameters are based on the anticonvulsant effect. There is no standard blood level recommendation for the treatment of bipolar disorder. The ideal therapeutic blood level is subjectively determined and depends on the patient's clinical response and the appearance of side effects. During the initial 6–8 weeks of treatment, blood levels may decrease despite maintaining a regular dose, due to carbamazepine's ability to induce its own metabolism. Checking blood levels and adjusting appropriately is important for maintenance of the treatment effect. Geriatric patients may be able to maintain adequate therapeutic levels on lower doses (400–600 mg) due to slower metabolism.

Side Effects

Bone marrow depression (aplastic anemia, decreased cell counts, agranulocytosis) and hepatotoxicity can occur with carbamazepine. Risk of bone marrow depression is estimated at 1/125 000. Weekly monitoring of blood counts, liver profile and carbamazepine levels is indicated during the early weeks of treatment. Idiosyncratic reactions are rare; however, patients should be asked to report immediately reactions such as fever, sore throat or severe fatigue of sudden onset.

The most common adverse effects of carbamazepine are dizziness, drowsiness, vertigo, ataxia, diplopia, nystagmus and blurred vision[9]. These effects are usually dosage-related and may be minimized by reducing the dose. Skin rash, urticaria, Stevens–Johnson syndrome, Lyell's syndrome, photosensitivity and dermatitis have also been reported, so that carbamazepine should be discontinued if these symptoms appear.

Other side effects include cardiovascular complications, such as congestive heart failure, hypertension, hypotension, arrhythmias, AV block and thrombophlebitis[33] as may occur with other tricyclic agents. The risk is greatest if patients already have underlying cardiovascular disease.

Drug Interactions

Carbamazepine interacts with a variety of other medications. Serum carbamazepine concentrations are markedly increased when carbamazepine is given with SSRIs, erythromycin, isoniazid, calcium channel blockers and danazol. Blood levels will also increase to a lesser degree with cimetidine, valproate, phenobarbital, phenytoin and theophylline. Carbamazepine decreases neuroleptic blood levels, which may lead to a lower efficacy of the neuroleptic in combined therapy.

Valproate (Valproic Acid)

Efficacy

Valproate is an anticonvulsant also shown to be effective in the treatment of bipolar disorder in the general adult population. It has also been documented to be effective for the elderly bipolar patient[34–44]. Valproate primarily works through the GABA system, and has recently been used to treat patients with acute mania who are resistant to traditional drugs such as lithium and carbamazepine[36,45]. It remains the drug of choice in patients who have failed to respond to lithium or carbamazepine or who are unable to tolerate these medications because of their side effects. Valproic acid may be used effectively in combination with lithium if there is only a partial response to either drug. Like carbamazepine, valproate causes minimal cognitive side effects, which is of particular advantage in the elderly patient.

Treatment Considerations

Valproate appears to be very well tolerated by elderly patients. Prior to starting patients on valproate, liver function tests and a CBC should be performed. Albumin levels should be performed on the frail elderly. Valproate may be used in combination with lithium, although experience suggests that a trial of monotherapy is usually indicated initially[9].

Dose and Administration

Valproic acid is available in three forms: valproic acid, sodium valproate and divalproate sodium. Gastric irritation is not uncommon with valproic acid or sodium valproate treatment. In such patients, the use of divalproate sodium may reduce gastrointestinal (GI) irritability. This medication is available in three strengths, 125 mg, 250 mg and 500 mg. Treatment should begin with low divided doses (125 mg twice a day) and be gradually increased to 500–1000 mg/day, depending on tolerance, side effects and blood levels. Most studies evaluating the effectiveness of valproate in bipolar disorder have used the target drug concentrations found effective in the treatment of epilepsy (50–100 mg/ml)[46]. Higher blood levels may sometimes be required to achieve optimal clinical response.

Valproate is rapidly absorbed from the gastrointestinal system and has a half-life of 6–16 h in younger patients, although this could be longer in geriatric patients. In serum it is predominantly protein-bound after absorption. The decrease in serum albumin levels associated with aging may result in lower dosages being required for elderly patients to achieve adequate blood levels. It is metabolized in the liver prior to elimination.

Side Effects

Gastrointestinal side effects of valproate include nausea, vomiting and indigestion. Occasionally abdominal cramps, constipation and diarrhea are reported. Anorexia has also been observed, although weight gain appears more common. These effects are

usually transient, diminishing with continued treatment. Persistent GI symptoms may respond to a reduction in the dose or changing to the enteric-coated form.

Common central nervous system (CNS) effects are sedation and ataxia, which are generally dose-related. Nystagmus, headache, diplopia and asterixis are less common side effects. Dizziness and lack of coordination can occur and are also dose-related.

Minor elevations of liver transaminases (SGOT, SGPT and LDH) can occur as side effects of treatment. Hepatotoxicity with hepatic failure has been reported in children but less frequently in adults. Baseline and periodic monitoring of hepatic function is indicated during the initial phase of treatment.

Idiosyncratic reactions may cause alopecia, which can be treated effectively with vitamin supplements containing zinc and selenium. Other side effects, such as thrombocytopenia, leukocytosis, edema, weakness and skin rash, have been reported but are generally rare.

Drug Interactions

Because valproate is extensively metabolized in the liver, it may interact with other medications. Valproate may inhibit the metabolism of phenobarbital, ethosuximide, phenytoin and some tricyclic antidepressants, resulting in higher blood levels of these drugs. Frequent monitoring of blood levels and appropriate adjustment of dosage may be needed to maintain therapeutic blood levels during the initial stages of treatment. Combinations of valproate and clonazepam may produce lapse of memory, which could present a significant problem in elderly patients. The use of anticoagulants such as aspirin and warfarin should be closely monitored, as the potency of these drugs may be enhanced.

Newer Anticonvulsants

Gabapentin

Gabapentin is a novel anticonvulsant agent structurally related to γ-aminobutyric acid (GABA), currently approved as an adjunctive therapy in patients with partial seizures. Its mechanism of action is not yet fully understood. Gabapentin has been increasingly used for the treatment of bipolar disorder, behavioral disturbances in Alzheimer's disease, and social phobia. Multiple case reports and small open-label studies in the general adult population have demonstrated gabapentin to be effective as monotherapy or as an adjunct therapy for the treatment of acute mania, or as a prophylactic therapy for bipolar illness[47–52]. Experience in the non-demented elderly bipolar patient is limited.

Gabapentin is not metabolized and is not protein-bound. It is excreted in the kidneys essentially unchanged. It has few pharmacokinetic interactions with other medications. Some researchers have reported a small increase in Depakote levels when used together[53]. Gabapentin is not associated with any hematologic or hepatic problems and does not require monitoring of serum concentration. In addition, gabapentin has a relatively benign side-effect profile. The most commonly reported adverse effects are sedation, dizziness, ataxia and fatigue[54]. These are usually minor and transient. These properties have made gabapentin a very attractive medication choice for use in bipolar patients who are receiving multiple medications, experience blood or liver problems, or in whom blood level monitoring is a problem[55]. Some researchers[51], however, have suggested that gabapentin may only exert a ''moderate'' antimanic effect, and that its onset of effect may be delayed when compared with other mood stabilizers. Thus, gabapentin may be less effective in the acute treatment of mania, and is recommended as adjunctive therapy in severe mania.

The effective dose of gabapentin in the treatment of bipolar disorder is not yet known. Most trials in young adults have used a dosage range of 300–2400 mg/day, although the use of larger doses has also been documented. Ferrier[55] has suggested that gabapentin may be particularly efficacious in rapid-cycling bipolar disorder (dose range 1500–2400 mg/day). Elderly patients would presumably require less, due to age-related decreases in creatinine clearance. The usual starting dose is 300–600 mg/day in divided doses.

Lamotrigine

As the use of anticonvulsant medications for treatment of bipolar disorder has proved successful, other anticonvulsants have also been increasingly used. Lamotrigine is an anticonvulsant approved as an adjunctive treatment for refractory epilepsy. The exact mechanism of action is not yet known, although evidence suggests that it reduces the release of excitatory amino acids (by blocking voltage-dependent sodium channels) and may act as a calcium channel antagonist[56,57]. Early studies and case reports in young adults have suggested that lamotrigine may be useful as a monotherapy or as an adjunctive therapy for bipolar disorder[58–61,95,96,98] and is particularly effective in rapid-cycling bipolar disorder and bipolar depression[62–66]. Lamotrigine has not been studied in elderly bipolar patients.

Lamotrigine is metabolized in the liver, with a half-life of 25–30 h. Protein binding is 55%. Lamotrigine does not appear to induce the P450 system and it has little interactions with other psychotropic medications. However, carbamazepine may decrease lamotrigine levels while valproate may increase them.

The most common side effects are headache, nausea, diplopia, dizziness and ataxia. A skin rash may occur in 5% of patients, more commonly with older age, rapid escalation of dose and the concomitant use of valproate. In most cases the rash is mild and transient; however, a few patients have developed Stevens–Johnson syndrome. Therefore, the medication is usually titrated very slowly (beginning at 12.5 mg/day) and is discontinued if a rash develops. Lamotrigine has also been reported to cause confusion or psychosis or to induce mania. There are no current standard dosage recommendations and routine measurement of serum concentrations is not required.

ADJUNCTIVE MEDICATIONS FOR ACUTE MANIA

Clonazepam

Efficacy

Clonazepam is a nitrobenzodiazepine derivative indicated in the treatment of absence seizures, infantile spasms, myoclonus and atonic seizures. It has proven efficacy in reducing seizure frequency and has also been used effectively in restless leg syndrome, panic disorder and Tourette's disorder. Clonazepam has also been used with success in treating acute mania[67,68]. It has also been used to augment mood stabilizers during the acute treatment of manic episodes, allowing a decrease in the use of neuroleptics in non-psychotic mania[69–71]. Clonazepam has not been well studied for use in geriatric patients with bipolar disorder.

Dose and Metabolism

The antimanic effect is attained in younger adults with a dose range of 2–16 mg/day in divided doses[67]. The half-life in younger

adults is 20–80 h. Older patients require much lower doses for clinical efficacy because of delayed metabolism and therefore a much longer half-life. A clinical response is usually seen in the dose range 2–6 mg in divided doses in such patients.

Side Effects

The most common side effects are ataxia, disinhibition, drowsiness and sedation. A paradoxical effect (excitation, agitation, irritability) has been observed, and is more likely to occur in patients with underlying neurological illness. Clonazepam can potentiate other sedating drugs, such as antihistamines and alcohol.

Benzodiazepine use is always recommended as short-term therapy only. Patients maintained on clonazepam may develop tolerance and dependence after 6 months of consistent use. The use of benzodiazepines in the elderly is of special concern, due to the potential to cause decrease in cognition, alertness or balance. Clonazepam should always be gradually tapered to avoid withdrawal symptoms.

Lorazepam

Efficacy

Lorazepam is a short-acting benzodiazepine that has proved effective in the treatment of acute mania[72,73,97,99]. Lorazepam is frequently used as an adjunctive medication for the control of symptoms of acute mania until the mood-stabilizer becomes effective. Like clonazepam, the use of lorazepam has decreased the use of neuroleptics for agitation during the acute manic episode[74,75]. This medication is not indicated for maintenance treatment. The use of lorazepam in the elderly bipolar patient is not well studied.

Dose and Metabolism

Lorazepam is available in both oral and intramuscular forms, and absorbed rapidly with either route of administration. It is the most common benzodiazepine used in geriatric populations due to its short half-life (10–20 h), large therapeutic index, no metabolites, gluconoride conjugation and rapid onset of action. The dose range is generally 1–4 mg/day in divided doses for a geriatric population, titrated by individual response side effects.

Side Effects

Like all benzodiazepines, increased and persistent sedation may increase the risk of falling, especially in the elderly. Paradoxical behaviors and disinhibition can occur in a small percentage of patients, most commonly those with underlying neurological illness. Lorazepam also potentiates other sedating drugs; therefore, close monitoring is required when using lorazepam in the elderly.

ANTIPSYCHOTIC MEDICATIONS

Acute manic episodes of moderate to severe degree, or manic episodes associated with symptoms such as hallucinations, delusions, paranoia or severe irritability or agitation, can be treated initially with antipsychotic medications. Most typical antipsychotic medications effect clinical improvement by blocking dopamine pathways in the brain and provide sedation through antihistamine effects. Atypical antipsychotic medications are thought to effect clinical change through a combination of dopamine-blocking effects and serotoninergic activity. Clozapine, risperidone and olanzapine have been reported to be effective in the treatment of acute mania, both as single agents and in adjunctive treatment[76–81]. These studies, however, have not involved elderly patients.

High-potency typical antipsychotics tend to cause significant extrapyramidal symptoms, such as rigidity, bradykinesia, tremor, dystonia, akathisia and a Parkinson-like syndrome, but a low incidence of hypotension, cardiovascular toxicity and sedation. Low-potency typical antipsychotics cause significant sedation, postural hypotension and peripheral anticholinergic effects. The newer atypical antipsychotics have less severe side effects, but still may cause sedation, orthostasis or extrapyramidal side effects. Given the high risk of such side effects in geriatric patients, low-potency neuroleptics should generally be avoided. The atypical antipsychotics are increasingly being used, due to their preferred side-effect profile. The use of antipsychotic medications in conjunction with other medications appears to have limited adverse interactions; however, a few studies have reported the development of neurotoxicity from the combined use of typical antipsychotic medications and lithium[82–84].

Geriatric patients typically require lower doses than middle-aged patients. Lower doses also minimize important side effects, particularly the risk of tardive dyskinesia in the long-term use of neuroleptics. Once acute symptoms improve, the antipsychotic dosage can be lowered or even discontinued while stabilizing patients on antimanic medications.

ELECTROCONVULSIVE THERAPY (ECT)

Electroconvulsive therapy (ECT) has been shown to be a highly effective treatment for acute mania[85–87]. Several studies of both geriatric and general adult manic patients have shown an improvement in approximately 80% with ECT[88,89]. This is especially significant, since ECT is frequently used for patients who have been resistant to other treatments or who have significant medical co-morbidities.

Contraindications

Even though there are no absolute contraindications for ECT, the risk of morbidity and mortality is increased in certain conditions. These include space-occupying intracerebral lesions or other conditions that may increase intracranial pressure, unstable vascular aneurysms or malformations, intracerebral hemorrhage, recent acute myocardial infarction or severe uncontrolled hypertension[90]. However, if ECT is required, risks can usually be minimized by pharmacologic treatment during ECT.

Risks and Adverse Effects

Usually, elderly patients tolerate ECT very well. The mortality rate for elderly patients is 0.01%, roughly the same as for the anesthesia induction itself[88,91,92]. Two-thirds of the deaths are from cardiac complications, such as ischemia, arrhythmias and transient severe increases in blood pressure. Most incidents occur immediately after the treatment or in the recovery period.

Side effects commonly observed during ECT include confusion and short-term memory loss. The latter is generally temporary, but occasionally some patients complain of prolonged loss, although no organic or irreversible changes in the brain have

been found[93]. The risk of confusion and memory loss tends to be associated with high stimulus intensity, bilateral electrode placement, increased number and/or frequency of treatments, older age and pre-existing cognitive deficiencies. Adjustment of the stimulus waveform, decreasing the stimulus intensity, using unilateral electrode placement or increasing the interval between treatment may decrease the cognitive side effects.

Other somatic side effects include headaches, nausea, and muscle soreness. Prophylactic treatment with analgesics or using an increased dose of the muscle relaxants during ECT may minimize these symptoms. ECT patients are also at a higher risk for falls.

Treatment Considerations

Prior to initiating ECT treatment, a focused medical history and physical examination is necessary to assess and minimize any potential risk factor. Laboratory tests should include a hematocrit or hemoglobin, serum electrolytes and an electrocardiogram (ECG)[90]. Most practitioners also obtain either an EEG, CT of the head, or brain MRI prior to ECT. If a patient has a history of musculoskeletal disease or osteoporosis, spinal X-rays may be obtained to evaluate the presence of underlying compression fractures, so that anesthetic/muscle relaxant medication may be properly adjusted. Dental evaluation is of particular importance in aged patients and attention should be given to patients who have loose teeth or none or only partial dentures.

An informed consent should be obtained prior to initiating ECT. In geriatric patients whose judgement and insight are compromised by their illness, the family should be involved in treatment decision making and consent. In the case of patients not competent to give consent, the legal guardian must be identified and approve consent.

The use of psychiatric medications during ECT should be minimized. Lithium should be discontinued prior to ECT, since it may increase the risk of status epilepticus and prolonged muscular blockade with succinylcholine. The anticonvulsants (valproate, carbamazepine) should also be discontinued, since they inhibit the ECT seizure. It should also be remembered that all benzodiazepines increase seizure threshold. They can be tapered prior to ECT or a benzodiazepine antagonist can be used just prior to the procedure.

Early reports suggested that mania was more resistant to ECT or required more frequent treatments than depression. Recent research has found this not to be true. The patient's clinical improvement is the best guide in deciding the optimal number of treatments. An average of 6–12 treatments is usually required for optimal response. Recommendations for treatment parameters may be found in several other texts[90,91,94].

Late-life Psychotic Disorders: Nosology and Classification

Lisa T. Eyler Zorrilla and Dilip V. Jeste

University of California, San Diego, and VA San Diego Healthcare System, CA, USA

The notion that mental disorders could occur in particular periods of life, such as old age, appeared only in the second half of the nineteenth century[1]. During this short history, there has been little agreement, and much confusion, regarding the nosology and classification of late-life mental disorders, particularly in the area of psychotic disorders.

One group of individuals with late-life non-affective psychotic disorders consists of those with onset of a psychotic illness (e.g. schizophrenia, delusional disorder) early in life, who have now aged. Debates about the classification of these patients have followed the same lines as those regarding younger adults (e.g. degree of overlap between psychosis and affective disorders, issues of duration and course) but most would agree that these patients should retain their original diagnosis into old age unless symptoms change dramatically enough to warrant a different diagnosis. A second group of patients consists of those individuals with new onset of non-affective psychosis late in life. In a majority of such cases, psychosis is secondary to a general medical condition such as dementia. There has been little controversy about the classification of these "organic" psychoses in the elderly, and this group of individuals will not be discussed further in the present chapter. In contrast, the classification systems for late-onset non-affective, non-organic psychoses are replete with overlapping terms, multiple definitions of the same nomenclature and different methods of conceptualizing similar disorders. Only recently, with the publication of an international consensus statement[2], has at least the geriatric psychiatry community come to some agreement on a set of terms to describe late-onset psychotic disorders.

EARLY HISTORY

Kraepelin was one of the first clinical researchers to recognize that non-affective psychoses could arise in middle age or later in life. Although the term "dementia praecox", with its inherent emphasis on an early age of onset, would seem to exclude late-onset cases, Kraepelin himself reported that one-third of his patients had symptom onset after age 30[3]. Kraepelin also studied a group of patients he described as suffering from "paraphrenia". This term had been used earlier by Guislain as a synonym for the syndrome of "folly"[4] and was used by Kraepelin to characterize a group of patients with minimal volitional and affective disturbance, prominent paranoia and a relatively preserved personality. While some of the subgroups of paraphrenia he described had a relatively later age of onset, Kraepelin did not consider paraphrenia to be exclusively a late-onset disorder. Furthermore, follow-up studies of these patients showed that they did not differ greatly from those classified as dementia praecox[5,6]. Thus, many of Kraepelin's followers ultimately came to believe that dementia praecox and paraphrenia were the same disorder and that this disorder could arise early or late in life.

Other clinician investigators working during this time, however, felt that psychotic disorders arising for the first time in late life should be classified separately. The history of these classifications has been thoroughly reviewed[7]. Gaupp[8] distinguished between dementia praecox and a disorder diagnosed for the first time in post-menopausal women that was characterized by depressive agitation, resulting in "mental weakness". Stransky[9] used the term "dementia tardiva" to describe late-onset dementia praecox. Some authors emphasized the prevalence of paranoid symptoms among those with onset of psychosis late in life by using terms such as "paranoia chronica"[10] or "involutional paranoia"[11]. Following this tradition, Albrecht's[12] classification of late-onset psychotic patients distinguished between patients with paranoid symptoms and little personality disturbance ("presenile paraphrenia") and those with "depressive madness resulting in imbecility". The latter category seemed somewhat similar to a late-onset form of dementia praecox. Others who described syndromes of late-onset dementia praecox used the terms "involutional paraphrenia"[13], "stiffening involutional psychosis"[14] and "paraphrenia"[15]. Unfortunately, the use of "paraphrenia" to indicate an age of onset distinction led to a great deal of later confusion. Some psychiatrists employed the term to indicate a separate phenomenology independent of age of onset (much like Kraepelin's original use; e.g. Leonhard[16]), while others used that diagnosis to encompass most late-onset psychoses.

1940–1970

Using his father's term for dementia praecox, "schizophrenia", Manfred Bleuler[17] described individuals with "late-onset schizophrenia" as those with onset after age 40 exhibiting symptoms similar to those with an earlier onset of the disorder and no evidence of brain disease. Very few of these patients had onset after the age of 60. This classification was adopted by most subsequent German authors[7].

In the UK during this period, however, the classification of late-onset psychotic disorders took a somewhat different path. Studying a group of patients with onset after age 60, Roth and

Principles and Practice of Geriatric Psychiatry, 2nd edn. Edited by J. R. M. Copeland, M. T. Abou-Saleh and D. G. Blazer

Morrissey[18] described a syndrome of paranoid delusions and hallucinations in the context of preserved intellect, personality and affect. Because of the phenomenological similarity to Kraepelin's "paraphrenia" and due to its late onset, Roth and colleagues termed this disorder "late paraphrenia"[19,20], a name that was designed to encompass all late-onset, non-affective, non-organic psychoses in which paranoid symptoms were prominent. Thus, the term was both broader than late-onset schizophrenia, in that it encompassed late-onset delusional disorder, and more restrictive, in that it did not include non-paranoid forms of late-onset psychosis. Post[21] developed a different descriptive system. He divided late-onset (after age 50) psychoses into paranoid hallucinosis, schizophreniform syndrome, and schizophrenic syndrome. Based on a 3 year follow-up, however, he concluded that these three diseases were actually a continuum of the same disorder with slightly different symptom profiles.

European debates and developments were slow to influence the classification system used in the USA. The first *Diagnostic and Statistical Manual of the Mental Disorders* (DSM-I)[22] used the term "involutional psychotic reaction", which encompassed both paranoid ideation and depression in older patients. This amalgam of affective and psychotic symptoms in the elderly was split in the second edition (DSM-II)[23] in favor of "involutional paranoid state (involutional paraphrenia)" and "involutional melancholia". The former disorder, like Roth's late paraphrenia, was characterized by "delusion formation with onset in the involutional period . . . The absence of conspicuous thought disorders typical of schizophrenia distinguishes it from that group"[23]. Schizophrenia could be diagnosed in individuals with any age of onset.

1970–PRESENT

As European psychiatrists began to study patients with late paraphrenia more systematically, new classification systems in the USA were restricting the diagnosis of late-onset psychosis. One of the five Feighner Research Criteria[24] for schizophrenia was age of onset before age 40. In the third edition of the DSM (DSM-III)[25], a diagnosis of schizophrenia could not be made if the onset of symptoms was after age 45. Late-onset psychosis that involved persistent persecutory delusions with prominent hallucinations could be given a diagnosis of "paranoid disorder". This classification system was in stark contrast to both earlier RDC criteria[26] and to the 9th version of the *International Classification of Diseases* (ICD-9)[27], neither of which imposed age-of-onset restrictions for schizophrenia. The ICD-9 also allowed for a diagnosis of paraphrenia at any age. The revised version of DSM-III (DSM-III-R)[28] rectified the omission of late-onset schizophrenia by providing a separate diagnostic category for those diagnosed with schizophrenia after age 45. In the most recent version of the DSM (DSM-IV)[29] and the ICD (ICD-10)[30], no special categories exist for late-onset psychoses, although schizophrenia may be diagnosed at any age.

TOWARD A CONSENSUS

It is clear from this historical review that there has been little consensus regarding the classification of late-onset non-affective non-organic psychoses. Two opposing lines of thought have pulled the terminology in different directions. On the one hand, some authors have preferred to emphasize the similarity of late-onset psychoses to the corresponding early-onset disorders. This has resulted either in the use of terms such as "late-onset schizophrenia" and "late-onset delusional disorder" or has prompted a move toward ignoring age of onset altogether in classification (e.g. DSM-IV, ICD-10). On the other hand, some members of the psychiatry community (mainly those in the UK) have preferred to emphasize differences between the phenomenology of late- and early-onset psychosis and thus have tended to use distinct terminology, such as "paraphrenia" or "late paraphrenia".

Thus, questions remain about which terminology would optimally serve the clinical and research communities. There are at least two overlapping issues to consider. First, how similar or different is the late-onset, non-affective, non-organic psychosis from early-onset disorders? If late-onset patients are no different from early-onset patients in terms of demography, phenomenology, etiological factors, prognosis and treatment, then it would be redundant to classify them in a separate category. If, however, such features differ between early-onset and late-onset individuals, then it would seem important to preserve a distinct diagnostic category in order to encourage further research and allow for optimal prognostic evaluation and treatment. The magnitude or extent of the differences between early- and late-onset individuals should also influence the terminology chosen for the diagnostic categorization. If a majority of critical clinical features are shared with an early-onset disorder, then it would make sense to adopt a term such as "late-onset schizophrenia". If the extent of differences is sufficiently large, a separate term would be warranted. A second issue to consider in determining the best classification scheme is what age of onset should be called "late". Most of the American studies of late-onset non-affective, non-organic psychosis have included patients with onset after 45 and generally before age 65. In addition, among the patients in Bleuler's late-onset schizophrenia studies, only 4% had an onset after age 60[7]. In contrast, most studies of late paraphrenia have been conducted with patients whose onset was after age 65. Differences in age-of-onset between late-onset schizophrenia and late paraphrenia studies may help to explain some of the diagnostic confusions that have persisted.

Only recently has the weight of evidence become sufficiently great in the field of late-life psychoses to allow for adequate consideration of these issues. In July 1998, the International Late-Onset Schizophrenia Group met to present reviews of published data on late-onset non-affective, non-organic psychosis and to develop a consensus statement regarding diagnostic categories[2]. The statement recognizes two illness classifications: late-onset (onset after the age of 40 years) schizophrenia and a very-late-onset (onset after 60) schizophrenia-like psychosis. Thus, the group determined that it was important to recognize a diagnostic distinction based on age of onset, due to differences between late- and early-onset patients, but that the disorders were not sufficiently different to warrant a separate nomenclature. In addition, the group felt that a further distinction was warranted within late-onset patients between those with onset in middle age and those with very late onset, based on major differences between these groups.

The similarities and differences among early-onset schizophrenia, late-onset schizophrenia and very-late-onset schizophrenia-like psychosis are summarized in Table 89.1. There are many areas of similarity between both late-onset groups and early-onset schizophrenia, such as symptoms[31–33], family history[32], brain imaging findings[34–36], and the nature of cognitive deficits[35]. The decision to retain the word "schizophrenia" in the nomenclature of both disorders was driven by these strong similarities. On the other hand, the consensus statement's distinction between those with middle-age-onset and old-age-onset psychoses was motivated by epidemiological, etiological and symptom differences between these two groups. Very-late-onset schizophrenia-like psychosis is different from both early- and late-onset schizophrenia, in that these cases tend to be associated with sensory impairment and social isolation[20], are less likely to exhibit formal thought disorder and

Table 89.1 Comparison of typical-onset (age 15–40) schizophrenia, middle-age-onset (age 41–65) schizophrenia, and very late-onset (age >65) schizophrenia-like psychosis

affective blunting but more likely to have visual hallucinations[26,34,37] and have less familial aggregation of schizophrenia[40]. It should be emphasized that the members of the International Late-onset Schizophrenia Group were not unanimous in their support of the particular age cut-offs given in the consensus statement and also felt that the proposed nomenclature was not an end but a beginning of future research into this important topic.

Late-onset schizoaffective disorder and late-onset delusional disorder are not specifically addressed in the consensus statement. Based on recent research[38], late-onset schizoaffective disorder appears to share a majority of critical clinical and demographic features with late-onset schizophrenia. Thus, late-onset schizoaffective disorder appears to be a subgroup of late-onset schizophrenia in which mood symptoms are also present. Late-onset delusional disorder, by contrast, can be distinguished from late-onset schizophrenia by a unique preoccupation with non-bizarre delusions in the context of preserved affective and personality functioning in other domains[29]. In addition, treatment of these individuals may be more challenging than in schizophrenia due to a difficulty in establishing rapport with therapists[39]. Cognitive function, however, is somewhat more preserved in older patients with delusional disorder than in those with schizophrenia[39]. Unfortunately, there is a lack of research comparing early- and late-onset delusional disorder.

Further research is needed to clarify the classification of late-onset psychotic disorders. Specifically, longitudinal follow-up studies are necessary to determine whether the course of illness is different in the three groups of patients and how the course of late-onset disorders compares to that of early-onset syndromes. Such an enterprise is greatly aided by the consensus classification recently proposed. In summary, despite a tumultuous history, the future for research and clinical work in late-onset psychotic disorders appears to be on firmer footing for the new millennium.

Clinical Assessment and Differential Diagnosis

D. N. Anderson
Mossley Hill Hospital, Liverpool, UK

The schizophrenias of late life, previously called late paraphrenia[1] and paranoid states in old age, present fascinating, complex, biopsychosocial problems that span the whole of psychiatry and medicine. The characteristic features of late-onset schizophrenia have been summarized by several authors[2–10], although never better than in the seminal paper by Kay and Roth[2].

These conditions usually present with paranoid ideation, most commonly persecutory in nature, with or without other schizophrenia-like symptoms. The central abnormality implied by the term "paranoid" is a morbid distortion of beliefs, but not all distorted beliefs are delusions and not all elderly people expressing them are mentally ill. Many aspects of old age increase vulnerability, exposing elderly people to abuse and victimization, and a sensitive appreciation of this situation is needed when assessing the paranoid elderly patient.

Furthermore, not all patients with delusions have schizophrenia[11] and the first aim of assessment will be to clarify the nature of paranoid symptoms and consider a differential diagnosis. In most cases a diagnosis will be clear from the detailed historical account of symptoms and their course, abnormalities of mental state and simple physical investigations. Assessment must, then, evaluate the individual's level of functioning, independence, vulnerability, social and family support and physical health, which will all be of relevance to aetiology and management. The assessment will aim to consider patients and their symptoms within the wider context of their social environment, physical and psychological limitations. It is, therefore, necessary to have knowledge of premorbid personality, life style, life experience and cultural background, remembering that young and older generations have important cultural differences.

Ideally, the assessment will take place in the patient's home, when environment may be maximally appreciated. Home assessment provides a more complete picture of the patient's circumstances and helps put the problem into a living context. Commonly, paranoid ideas in old age relate to the patient's immediate, local environment and people within it. Herbert and Jacobson[3] used the term "partition delusions" to describe the belief that things were happening just the other side of the wall, floor or ceiling. Post[12] found that paranoid symptoms often temporarily disappeared when the patient was removed from the hostile environment and this can give a misleading impression of their nature.

The floridly deluded and hallucinated patient is easily recognized, but in old age paranoid ideation may be almost plausible when complaints of being abused, victimized, stolen from or manipulated are not beyond the bounds of possibility. Trying to establish the validity of such claims requires observation and information from a variety of sources.

Table 90.1 Differential diagnosis

Depression
Mania
Schizoaffective disorder
Paranoid personality disorder
Factual (basis in fact)
Sensory impairment

We need, first, to consider the differential diagnosis of paranoid symptoms (Table 90.1) and how clinical assessment helps to differentiate diagnostic categories before discussing the process of assessment in more detail.

DIFFERENTIAL DIAGNOSIS

Christensen and Blazer[13] found the prevalence of paranoid ideas in a community sample to be 4%. Leuchter and Spar[14] retrospectively reviewed 880 psychogeriatric admissions and the 8% who suffered a first episode psychotic illness met DSM-III criteria for major affective disorder (36%), organic mental disorder (43%) and primary paranoid disorder (21%). The more common conditions will be reviewed briefly from the point of clinical differentiation, although for detailed consideration reference should be made to the relevant chapters.

Delirium (Acute Confusion)

The history is short, usually days or a few weeks, and the onset rapid. Paranoid ideas and hallucinations occur in 40–50%[15]. These are typically poorly organized, fluctuating and variable in content, while hallucinations most commonly occur in the visual modality. Other features of delirium will normally be present.

Dementia (Chronic Confusion)

Ballinger *et al.*[16] found delusions and hallucinations in 38% and 34% of 100 dementia admissions. The study by Burns *et al.*[17] of

178 Alzheimer patients revealed persecutory ideation (20%), delusions (16%) and hallucinations (17%) to be common. Fifty per cent of patients with multi-infarct dementia may have delusions at some time[18] and the clinical course of diffuse Lewy body disease is particularly characterized by paranoid ideation and hallucinations[19].

The manifestations of progressive, global, cognitive impairment will usually be present, although dementia may present with paranoid symptoms that can be indistinguishable from function illness[20]. Paranoid ideas are frequently related to cognitive deficits, especially memory, leading to accusations of theft[17] or problems arising from perceptual difficulties and misidentification[8]. Like delirium, these fluctuate and may be ferociously denied, or forgotten, at interview, although the theme and content remain fairly consistent.

Depression

If depression is of delusional proportions, biological and characteristic depressive symptoms are usually marked. Delusions and hallucinations, occurring in all sensory modalities, are normally mood-congruent but incongruent symptoms occur and may be difficult to distinguish from those of primary paranoid disorders.

Kay *et al.*[21] suggested six historical variables that help distinguish affective and paranoid psychoses: life events and family history of affective illness favoured an affective diagnosis, while low social class, few surviving children and social deafness favoured paranoid disorder. Premorbid personality proved the best discriminator, with paranoid patients being solitary, shy, touchy, suspicious and emotionally aloof, and patients with affective disorders reporting subjective ratings of high premorbid anxiety.

Mania

Traditional teaching suggested that mania in old age was both rare and atypical in presentation. Broadhead and Jacoby's[22] prospective study found that young and older-onset patients were clinically very similar. The onset of mania in old age is more common than once thought[23] and the majority of patients will have a history of affective disorder, some 50% having had three or more depressive episodes, with a latency of 15–17 years from first depression to mania[22–25].

Organic Delusional/Hallucinatory Disorder

Paranoid hallucinatory disorders have been associated with a variety of organic conditions[8,11,26–29] and pharmacological agents[5,8,11,30]. The symptoms may be typical of functional disorders[26,31] and the diagnosis depends on establishing a clear aetiological link and temporal relationships between a physical disorder or drug and mental disturbance. As Kay[32] put it, "Had the organic diagnosis not been reached independently of the psychiatric symptomatology, most of the cases would have been regarded as, indubitably, schizophrenic".

The more common causes encountered in clinical practice include hypothyroidism, intra- and extracerebral tumours, epilepsy and cerebrovascular disease, and pharmacological agents such as psychostimulants, anti-parkinsonian and dopaminergic drugs and steroids. Alcohol intoxication and withdrawal from alcohol, benzodiazepines and barbiturates may all cause paranoid states, and withdrawal syndromes should be particularly considered when psychosis develops shortly after a hospital admission.

Paranoid Personality Disorder

This is necessarily a life-long problem which must be demonstrable from early adulthood. It is characterized by a sensitive and defensive attitude that causes people to feel they are victims of life and interpret events in a self-referential way[14]. The effects of ageing and the vicissitudes of later life may accentuate these traits and, if dementia or functional illness supervene, will colour the symptomatology.

Late-onset Schizophrenia

Kay and Roth's[2] description of the characteristic features of this condition has never been surpassed. Schizoid and paranoid premorbid personality, reduced likelihood of marriage and fertility, living alone with few surviving relatives, and deafness contributing to social isolation, and a limited but significant hereditary predisposition for schizophrenia with female preponderance, all characterize this disorder. The whole range of psychopathology typical of schizophrenia may be evident, although personality is more often preserved and negative features less prevalent[2,3,20,33,34]. Roth and Kay[35] provide a thoughtful discussion of the apparent similarities and differences of the associated features of late- and early-onset schizophrenia.

Delusional Disorders

These are conditions characterized by a persistent, circumscribed delusional theme and if hallucinations occur they are not prominent. They are defined by their delusional content, which may be erotic, jealous, hypochondriacal, persecutory or grandiose. These conditions have not been the subject of systematic study in old age, when they are thought to be relatively rare[8]. Onset is usually in middle age but as patients normally function well outside their particular delusion and symptoms frequently persist they may present in old age. Unlike late-onset schizophrenia, delusional disorder seems not to be associated with premorbid paranoid personality or deafness[36], although querulent paranoia has been related to deviant personality structure[65]. Familially they appear unrelated to affective or schizophrenic illnesses[37,38]. Howard *et al.*[39] found dilatation of lateral and third ventricle volumes by magnetic resonance imaging (MRI) to be more a feature of delusional disorder than schizophrenia in old age, as defined by ICD-10 criteria.

A small retrospective study comparing paraphrenia (schizophrenia of late onset) with paranoia (delusional disorder of late onset) found cerebral infarction on CT brain scan to be a feature of paranoia rather than paraphrenia. Furthermore, social isolation and being unmarried was not a feature of paranoiacs, with cerebral infarction suggesting separate groups defined by organic or social associations. Response to antipsychotic drugs was worse for paranoia[40].

ASSESSMENT

Interview

Interviewing paranoid elderly people may be complicated by deafness, speech problems or visual handicap, so time and patience are essential. An informant history is mandatory and often several sources may be required.

It is crucial to establish the interview situation, explain its purpose, allay anxieties and put patients at their ease. The patients should decide whether they prefer to be seen in private or with a

confidant(e) as another's presence may equally inhibit or encourage the disclosure of sensitive material. For similar reasons an informant may wish to speak privately though discussions should never appear clandestine.

Deafness and communication problems should be openly acknowledged, hearing aids worn and working, and extraneous noise eliminated, otherwise false impressions of cognitive state may be formed[41]. If a patient is seen in a hospital setting, insist on a separate, quiet interview room, otherwise conversation will be inhibited and information lost. Posture and attitude convey sincerity, concern and how seriously problems are considered. The patient needs to form a trusting relationship, and a respectful, honest but never patronizing approach is normally accepted. A sympathetic hand can reassure and encourage an anxious or suspicious patient.

The importance of establishing a positive therapeutic relationship at this early stage cannot be overstated, as it can have far-reaching effects, not only for the openness of discussion but also for future compliance and prognosis[12].

History

The nature of psychotic symptoms, their form, content and course must be detailed. Late-onset schizophrenia may develop insidiously over months or a year or more[2,3], delusional depression over a few months, delirium over days and dementia over 1–2 years. The intensity of paranoid ideas and their effect on behaviour assist diagnosis and the evaluation of risk. Associated symptoms, particularly affective and cognitive, should then be elicited.

Current and past medical problems and their temporal relationship to the onset of paranoid symptoms must be clearly established, including visual or auditory failure. Aetiologically significant hearing loss in late-onset schizophrenia is typically of long duration, severe and due to bilateral middle ear disease, often originating in early life[42–45]. Details of prescribed and non-prescribed drugs, dosages and recent alterations are essential.

Previous episodes of mental disorder should be confirmed from medical records, when past diagnoses and response to treatment may quickly clarify a diagnostic dilemma. Careful enquiry might uncover past episodes of untreated, self-limiting illness[3,31] and changes in behaviour may date the onset of current problems.

Premorbid personality and behaviour are important because departures from these in old age usually signify the onset of a morbid process. Forty to fifty per cent of late-onset schizophrenics have schizoid or paranoid premorbid traits[2,3] and the diagnosis of personality disorder depends on establishing a life-long attitude, Brenes Jette and Winnett[46] emphasized the interaction of narcissistic personality traits and the psychosocial consequences of ageing in their psychodynamic formulation of late-onset paranoid disorder.

The genetic loading of schizophrenia in old age is less marked than with younger patients but a positive family history is often found[2,7,20,47]. Odd behaviour or suicide among family members may be discovered when formal psychiatric treatment is absent.

Current social circumstances and recent change are of relevance to aetiology and management. The schizophrenias of late life are particularly associated with social isolation, but rarely with precipitating life events[2,3]. Paranoid patients frequently have poor socioeconomic status and multiple difficulties[13] and social support has prognostic implications[12]. Enquiring about alcohol and drug abuse must not be avoided for fear of offending a respectable elderly person. The elderly are not without vice and may be less inclined to confess it.

Mental State Examination

The detailed psychopathology of these conditions is described elsewhere and only points relevant to the process of mental state examination will be mentioned here.

It is important to ensure that the patient understands the terminology used to elicit abnormal experiences and that a common language is being used. Eliciting paranoid and psychotic symptoms can be difficult, but with tact and careful choice of words most patients will participate in an exchange of ideas about their experiences. This must be an unthreatening process for the patient and it is unwise to challenge or trivialize complaints at an early stage. A neutral position is advisable until a firm relationship is established, when complaints may be gradually reframed so that they can be viewed by the patient as problems that can be relieved, rather than immovable realities that are not amenable to therapeutic intervention. Suggesting that "it's all imagination" will be considered insulting and the patient's confidence will be lost.

Insight is rarely retained and patients may not volunteer experiences if they interpret questions as purely an enquiry into the state of their health. Patients have limited ability to accept the presence of illness or recognize psychiatric experiences as pathological[48]. Needless to say, the mental state examination must be thorough.

Physical Examination

A complete physical examination should be performed routinely, with particular emphasis on neurological status and sensory function. The association between sensory impairment and late-onset schizophrenia[44,49] makes attention to this area important and remediable conditions may be found. Visual impairment, particularly due to cataracts, is often found in association with delusions and deafness[43,50] and visual hallucinations may be as much to do with ocular pathology as psychiatric diagnosis[51]. A particular form of acute, elaborate visual hallucinosis, the Charles–Bonnet syndrome, is usually related to eye disease or cerebral organic disorder[52]. Simple clinical interview and self-reporting seriously underestimate sensory impairment and more detailed ophthalmic and audiometric examination may be necessary[53–55]. A simple battery of laboratory investigations is required for all patients, including haematology, biochemistry, thyroid function, urinalysis and chest radiography.

Advanced neuroradiological techniques promise much for the future but have limited clinical application at the present time. Some authors recommend the routine use of computed tomography (CT) and MRI. These procedures frequently reveal structural cerebral abnormalities, including increased ventricular size and periventricular and deep white matter hyperintensities[56,57], although their clinical significance is uncertain[58,59] and they appear to bear little relationship to clinical state or outcome[60,61]. These findings have no diagnostic value and the role of neuroimaging in clinical practice, at present, is to exclude specific intracranial pathology, particularly space-occupying lesions suggested by clinical examination. Similarly, non-specific electrophysiological abnormalities are common[5] and the EEG will only be of value in a minority of cases.

Psychometric testing may provide a useful baseline measure that can be serially repeated when the possibility of dementia arises[62]. Psychometric testing certainly reveals cognitive deficits in late-onset schizophrenic patients, particularly affecting frontal lobe and memory function[56]. These rarely signify dementia[60] and are more like the deficits found with early-onset schizophrenia than Alzheimer's disease[56]. They do not correlate with severity of psychosis or other clinical parameters[60,62].

CONCLUSION

Most patients with late-onset schizophrenia or primary delusional disorders will be adequately and preferably managed from home[12,63]. The need to admit to hospital seems to be declining[64] and may be determined as much by social and physical factors or treatment compliance as degree of psychopathology. For the patient requiring more than outpatient treatment, a day hospital can provide the necessary facilities for more intensive assessment of mental state, physical health and functional level.

The multifactorial contributions from ageing, physical disability, sensory impairment and social factors demand a multiprofessional approach and all relevant disciplines must be available and involved[8]. The evaluation of these conditions requires clinical skill, rigorous attention to detail and an holistic approach. The accuracy of diagnosis and success of management will depend on the quality of initial assessment and if diagnostic doubts exist, treatment should be postponed until the situation becomes clear. Occasionally a diagnostic trial of treatment will be justified.

The paranoid disorders of old age are stimulating, complex, challenging clinical problems that encompass the breadth of psychiatry, medicine and social sciences and their assessment and management will continue to appeal to the enquiring clinical mind.

Aetiology, Genetics and Risk Factors

David J. Castle[1] and Robin M. Murray[2]

[1]*Mental Health Research Institute and University of Melbourne, Melbourne, Australia and* [2]*Institute of Psychiatry, London, UK*

There is considerable controversy about the classification of the late-onset non-affective psychoses, and their relationship to "typical" early-onset schizophrenia. Kraepelin delineated "paraphrenia", a late-onset delusional state with prominent hallucinations, as distinct from dementia praecox. Mayer performed a follow-up study of a number of patients diagnosed by Kraepelin as having paraphrenia, and found that a high proportion had a longitudinal course of illness similar to that of dementia praecox patients. This study challenged the distinction between paraphrenia and dementia praecox and, once the Bleulerian label "schizophrenia" had been widely adopted, "paraphrenia" became a neglected term.

The term was resurrected by Roth[1] as "late paraphrenia", although he used it to describe a rather different group of patients, namely those manifesting a paranoid delusional state with prominent hallucinations for the first time in very late life. Confusingly, ICD-9 retained Roth's category, relabelled it "paraphrenia", and subsumed it under "paranoid states"; this has been dropped altogether from ICD-10. Furthermore, definitions of "late onset" range from over the age of 40 (after Feighner *et al.*[2]) to over 60 (after Roth[1]). The 3rd edition of the American Psychiatric Association's *Diagnostic and Statistical Manual* (DSM-III) set an age cut-off of 45 years for schizophrenia, so that later-onset paranoid states were labelled "atypical psychosis" or "paranoid (delusional) disorder". The revised editions of the manual (DSM-III-R and DSM-IV) removed this age stipulation, and it is now widely believed that schizophrenia can manifest for the first time at any age.

These changing conceptions make comparison across studies difficult. In this chapter, we refer to studies where a 40 year or later cut-off is used. We employ the term "late paraphrenia" for those patients with an illness akin to Roth's description, with first manifestation usually after the age of 60. Delusional (paranoid) disorder is not specifically addressed here.

GENETICS

It is generally accepted that schizophrenia tends to run in families. Gottesman and Shields[3], pooling data from a number of family studies, calculated the average morbid risk for schizophrenia (broadly defined) in first-degree relatives of schizophrenia probands to be around 10%, compared with about 1% in the general population. Rates are generally lower when operational criteria such as those of DSM-III are applied, but the higher relative risk in first-degree relatives compared with the general population remains. Twin studies consistently report higher concordance rates for schizophrenia in monozygotic (MZ) compared with dizygotic (DZ) twin pairs, suggesting that, in part at least, this familial aggregation is due to genetic factors. This conclusion is supported by adoption studies, which show that biological risk for schizophrenia is carried with the proband, irrespective of family environment (i.e. "adopted-away" offspring).

Few studies have specifically assessed familial aggregation in late-onset schizophrenia (see Table 91.1) and these all have methodological shortcomings. Authors have often failed to give a clear definition of illness in either probands or relatives; standardized diagnostic instruments have not been employed; and assessments have not been blind to proband diagnosis. Furthermore, proband numbers are mostly small, and it is often unclear exactly how many family members were assessed, and whether adjustments were made for those who were not. Also, because of the late onset of illness, many family members (siblings, parents) would have died and thus have been unavailable for interview; it is also difficult to know whether relatives had passed through the period of risk for illness-onset. Controls have rarely been employed, reliance being placed on results from independent studies of earlier-onset patients, which have again used different methodologies and diagnostic criteria.

Thus, the conclusions that can be drawn are limited. Overall, studies of "late paraphrenia" patients show rates of schizophrenia in siblings that are intermediate between those for siblings of early-onset probands and the general population. The discrepancy in rates quoted for parents is probably due to problems in assessing the parental generation. Those studies with an earlier age cut-off report higher risks for schizophrenia in relatives approaching those in the relatives of early-onset probands. However, these studies have used broad, non-specific definitions of schizophrenia, and have thus probably overestimated rates. The very high rate in the study of Huber and colleagues (see Table 91.1) is probably due to the misdiagnosis of patients with affective disorders, as they report no relatives with affective illness. The more recent study of Howard *et al.*[4], who employed a controlled family interview methodology, is more sound. These researchers assessed lifetime risk of schizophrenia and other psychiatric disorders in 269 relatives of 47 late paraphrenia patients, and compared the rates with those in 272 relatives of 42 elderly general population controls. The results, shown in Table 91.1, reveal no difference in the risk between the two groups of relatives with respect to schizophrenia, but do show the relatives of the schizophrenia probands to have a significantly elevated risk of depression (16.3% vs. 4.4% in controls).

Kendler *et al.*[5] in a review of family and twin studies, found no strong consistent relationship between age at onset of schizophrenia and risk for the illness in relatives. However, they did not specifically investigate late-onset schizophrenia patients, and the

Table 91.1 Family studies in late-onset schizophrenia

Reference No.	No.	Age	Definition of illness	Risk of schizophrenia	Risk of affective disorder
53[a]	65	>40	Schneiderian first rank	Siblings: 9.8% Parents: 4.4% (9 of 24 late-onset)	Not stated
25	57	>60	"Late paraphrenia"	Siblings: 2.5% Parents: 0 Children: 7.3% Nephews/nieces: 3.1%	Not stated
14	93	>60	"Late paraphrenia"	5 relatives (2 late-onset)	16 relatives
43	45	>65	Systematized delusions with or without hallucinations	Siblings: 2.3% Fathers: 2.2% Mothers: 4.4%	Not stated
44[a]	110	>40	Schneiderian first rank	19.4%	0%
54[a]	62 cases: 58 early-onset controls	>50	Late- vs. early-onset schizophrenia (definition of illness not stated)	10.8% vs. 17.7% in early-onset patients	2.0% vs. 6.6% in early-onset patients
48	35 cases; 35 affective disorder controls	>44	"Persistent delusions" with no affective features	5 relatives vs. 3 relatives of controls	0 relatives vs. 12 relatives of controls
4	47 cases; 42 controls	>60	"Late paraphrenia" (cases) vs. non-psychiatric controls	Narrow age range (15–50 years): 1.3% in cases and controls; wide age range (15–90 years): 2.3% cases, 2.2% controls	21 relatives of cases vs. 6 relatives of controls ($p = 0.003$)

[a]Quoted by Volavka[55] (1985).

data reviewed here suggest that there may indeed be a gradient of familial risk, dependent upon age of onset of the proband. Such a notion is compatible with the idea that late-onset patients have a smaller genetic loading than those with early onset and thus require more "environmental events" to manifest the illness. This conception presumes a multifactorial "vulnerability/stress" or "continuum of liability" model of schizophrenia that is useful in as far as it produces testable hypotheses. For example, Holden[6], in a study of 47 cases of paranoid psychosis with onset after the age of 60, found that deafness, which is considered a risk factor for late-onset schizophrenia (see below), was inversely related to family history of psychiatric illness.

An equally parsimonious explanation for the intermediate family risk in late-onset probands is that it is due to the greater proportion of such patients who have a less genetic subtype of illness. For example, paranoid ideation is common in late-onset schizophrenia patients, and Tsuang and Winokur[7] and Tsuang *et al.*[8] have reported that patients with the paranoid subtype of schizophrenia have later onset and fewer affected relatives than do the more disorganized "hebephrenia" patients. Furthermore, at least some patients labelled "late-onset schizophrenics" have an organic illness (see below), and such patients would be expected to have a low family risk for schizophrenia. Also, the family loading for affective disorder found in some studies (see above) suggests that at least some patients with late-onset schizophrenia have aetiological links with affective disorder.

FEMALE GENDER

All studies of late-onset schizophrenia that have included both sexes have attested to an excess of women. Table 91.2 shows data from a representative sample of such studies, which confirm that this female excess is robust to more- or less-restrictive definitions of illness. This excess cannot be explained on the basis of the relative longevity of women.

What is also evident from the data in Table 91.2, is that the older the sample, the greater the female excess. Few studies have assessed gender differences in non-affective psychoses in an epidemiologically-based sample of patients, ascertained across all ages at onset. The Camberwell Register First Episode Study[9] afforded an opportunity to do this. The sample consisted of 91% of all patients ($n = 477$) with a non-affective psychotic disorder, from a defined catchment area, who made their first contact with the psychiatric services over the period 1965–1984. Patients were rediagnosed according to a range of operational definitions for psychotic disorders, using the OPCRIT diagnostic system. Age-at-onset incidence curves were established for both sexes, using the base population figures as the denominator. Not only was the mean age at onset later for females, but the distributions of onset age for the two sexes were not isomorphic; males showed a dramatic early peak and a lesser mid-life peak, whilst females showed three peaks of onset, one in very late life. When subjected to an admixture analysis, the distributions for males showed two age distributions, with modal ages at onset of 21 and 39 years, whilst for females there were three distributions, with modal onsets at 22, 37 and 62 years[10].

A possible explanation for the female excess in late-onset schizophrenia is that female schizophrenia patients are somehow "protected" from the manifestations of disease at earlier ages. For example, Seeman[11] has suggested that the antidopaminergic action of oestrogen has such a protective function, with the illness manifesting perimenopausally when oestrogen levels fall. This theory gains support from animal and clinical studies that show that oestrogen has antidopaminergic properties. However, as described above, the incidence curves for schizophrenia in women do not mirror the menopausal fall in oestrogen levels, and the disease can manifest for the first time at very advanced ages.

A further consideration in attempting to explain the female excess amongst late-onset schizophrenia patients is the fact that the brains of males and females age differently. Of particular interest is the differential rate of loss of dopamine D2 receptors, with loss being more precipitous in men than in women. Thus, young males have a relative excess of D2 receptors compared with females, but in older females this gender difference is reversed[12]. This differential loss of D2 receptors between the sexes could conceivably play a part in the vulnerability of females to the manifestation of schizophrenia in late life and might also account, in part at least, for the particular female vulnerability to the development of tardive dyskinesia on exposure to neuroleptic medication in late life.

Table 91.2 Selected series of late-onset schizophrenia patients reporting gender ratio

Reference No.	No. of cases	Ascertainment method	Diagnosis	Age (years)	Ratio female:male
25	57	Hospital admissions	Late paraphrenia[a]	>60	5.3:1
43	47	Hospital admissions	Systematized delusion ± hallucinations; not demented	>65	22.5:1
44	644	Hospital admissions	Late-onset schizophrenia; not organic	>40	1.8:1
45	6064	First admissions	ICD-8 schizophrenia	>40	1.6:1
46	320	Hospital admissions	Late paraphrenia[a]	>65	6:1
47	25	Consecutive referrals	Late paraphrenia[a]	>60	3.2:1
48	35	Hospital admissions	Persistent delusional state; absence of mood or cognitive disorder	Onset >40	10.7:1
49	106	First admissions	ICD-8 schizophrenia, paranoid state, reactive psychosis, other psychoses	>60	2.2:1
6	37	Case register	Late paraphrenia[a] (13 cases considered "organic" at follow-up)	>60	7:1–3:1[b]
50	477	Case register	ICD-9 schizophrenia and related disorders, paraphrenia, atypical psychoses	>60	4.4:1
51	47	Referrals from a number of psychiatric settings	Late paraphrenia[a]	>65	9:1

[a]Akin to Roth's[1] criteria.
[b]Dependent on whether "organic" cases included.
From ref. 52, with permission.

PREMORBID CHARACTERISTICS

It has been consistently reported that a higher proportion of patients with late-onset paranoid psychoses have abnormal premorbid personality traits, most commonly described as "suspicious", "hostile" and "reclusive". Some workers have considered that the occurrence of paranoid psychosis in individuals with such personality traits is an "understandable transition", while Retterstol[13] has suggested that psychotic breakdown is a reaction to stress in a "hypersensitive" personality. Post[14] proposed that the paranoid/schizoid personality traits reflect a long-standing latent schizophrenic disorder that manifests itself only when additional factors come into effect. Such factors might include social deprivation, sensory deprivation (deafness and possibly visual loss, as discussed below), frank cerebral pathology, or even ordinary ageing processes in the brain. Moreover, such personality traits could be expected to result in social isolation and reclusiveness, which in turn would exacerbate the paranoid imaginings characteristic of the illness.

In contrast to their early-onset counterparts, late-onset schizophrenia patients are generally neither educationally nor occupationally compromised. This again suggests that they may have a form of disease that is relatively distinct from the severe early-onset "dementia praecox" type.

SOCIAL ISOLATION

Ageing often results in increasing social isolation. It appears, however, that patients with late-onset schizophrenia have a greater likelihood of being socially isolated than age-matched normals or affective disorder patients. Low rates of marriage, few offspring and paranoid premorbid personality traits could all be expected to contribute to such isolation. Paranoid ideation in the disease itself is often directed at neighbours, resulting in further reclusiveness. Thus, social isolation in late-life psychosis might well be a consequence rather than a cause of the illness.

SENSORY DEFICITS

A number of general population studies have found an association between paranoid ideation and sensory impairment in the elderly. This perhaps understandable association has also been investigated as potentially causal in late-onset paranoid illnesses. For example, Post[14] reported that 25% of 72 elderly paranoid psychotic patients had hearing loss, compared with 11% of an affective disorder group; the mode of audiometric assessment was not stated. Cooper *et al.*[15] found that 25 (46%) of a group of 65 elderly paranoid patients were "socially deaf", compared with 12 (21%) of 67 patients with affective illness. Audiometry and otological examination of an enlarged sample (27 paranoid and 18 affective deaf subjects) revealed that the paranoid group were more likely to have long-standing conductive hearing loss, as opposed to later-onset sensorineural loss in the affective group. Visual impairment, mostly due to cataracts, was found in 30 (56%) of 54 of the paranoid group, and 21 (37%) of 57 of the affective group.

From such data, Kay *et al.*[16] and Cooper[17] concluded that in the elderly, long-standing conductive deafness is an independent risk factor for paranoid, as opposed to affective, psychosis. This probably does not apply in earlier-onset schizophrenia patients, neither are persons with profound (prelingual) deafness predisposed to schizophrenia. The association with visual impairment is less robust, possibly because determination of functional visual impairment is difficult.

More recently, however, Prager and Jeste[18] failed to confirm an excess of constitutional ("uncorrected") visual and hearing impairment in late-onset schizophrenia patients; they did, however, find that such patients were more likely than controls to have sensory deficits that were not adequately "corrected", e.g. by spectacles or hearing aids. Thus, these data are complex and interpretation of causality problematic. Furthermore, there is no consistent association between particular modalities of sensory loss and any specific psychotic symptom. For example, it is not the case that hearing impairment is necessarily associated with auditory hallucinosis. Likewise, the association between visual impairment and visual hallucinations, so dramatically represented in the Charles–Bonnet syndrome[19], does not appear to be found in late-life schizophrenia.

The social and psychological consequences of sensory impairments (social withdrawal and ostracization; misinterpretation of social cues) may result in suspiciousness and hostility, leading to paranoid ideation. Abnormal percepts associated with reduced sensory input might result in hallucinations, as in the Charles–Bonnet syndrome, although secondary delusional elaboration is

considered unusual in such settings[19]. Moreover, Watt[20], in a study of 35 patients, found no association between hearing loss and paranoid psychosis manifesting in middle life. It might be that psychosis occurs only in individuals who are already prone to paranoid ideation, e.g. by virtue of mild cerebral damage. This is consonant with findings in an elderly general population sample[21], of an association between persecutory ideation, sensory impairment and cognitive dysfunction.

"ORGANIC" FACTORS

Acute paranoid ideation may result from cerebral or extracerebral organic factors, and the elderly are especially susceptible to such effects. More persistent delusional persecutory states are seen in association with a wide variety of structural brain changes and systemic toxic and metabolic disturbances. In particular, such states can occur in dementia. For example, Wragg and Jest[22], in a review of studies reporting the prevalence of psychotic phenomena in patients with Alzheimer's disease, found a rate of delusions of anything from 10% to 73% (aggregating to 30–38%, with a median of 33.5%). For hallucinations, the range was 21–49% (mean 28%). The importance of organic factors in the aetiogenesis of psychotic phenomena in the elderly is underlined by general population studies, which have consistently found the strongest predictor of paranoid ideation in the elderly to be cognitive impairment[23,24].

Kay[25] stated that a diagnosis of late-onset schizophrenia can be made only in the absence of "gross and persistent disorientation in time and place or severe failure of memory". Roth[1] claimed that his follow-up data validated the separation of such disorders from the dementias, while Kay and Roth[26] found only minimal evidence of organic cerebral damage in their late paraphrenic patients. Subsequently, Kay[25] reported survival rates for late paraphrenia patients of 0.97:1 (observed expected), compared with 0.3:1 for patients with dementia.

However, it is becoming increasingly clear that a significant number of elderly patients with "functional" paranoid states *do* have evidence of organic cerebral deterioration, not part of ordinary ageing. For example, Post[14] reported that some 15% of his patients were demented at follow-up, while Holden[6] found that 13 (35%) of 37 late paraphrenia patients had demented within 3 years of diagnosis; the only distinguishing feature on admission was a slight impairment on psychometric assessment in the "organic" group.

Neuroimaging investigations have revealed structural brain changes in a proportion of elderly patients with persistent psychosis and no obvious neurological or neuropsychological deficit. Miller and colleagues[27] reported three such patients who had CT scan evidence of cerebral infarction and one with normal pressure hydrocephalus. In a prospective CT and MRI study of 27 patients with late-life psychosis, Miller *et al.*[28] found silent vascular lesions in five (19%); subcortical frontal connections were most commonly involved. Similarly, Jernigan *et al.*[29] reported 13 patients with late-onset psychosis (10 schizophrenia, three delusional disorder) to have significantly more white-matter pathology on MRI than age-matched normal controls; and Breitner *et al.*[30] found significant leucoencephalopathy, especially affecting the temporoparietal and occipital regions, in eight late-onset schizophrenia patients; such lesions were minimal or absent in controls.

These findings may provide useful information about the pathogenesis of late-onset schizophrenia. However, the exact relationship of the reported lesions to the manifestation of the disease is unclear. There is little consistency in the site of the lesions, and white-matter changes have also been reported in elderly patients with severe depression[31]. Moreover, it appears that when late-onset schizophrenia patients are clinically screened fastidiously, so as to exclude any patients with potential "organic" aetiologies, they show no excess of white matter abnormalities compared to controls[32].

NON-SPECIFIC STRUCTURAL BRAIN ABNORMALITIES

Numerous neuroimaging studies have revealed an increase in ventricular:brain ratio (VBR) in younger schizophrenia patients compared with normal controls. These findings, and those suggesting temporal lobe dysplasia, appear to have a developmental origin. There are few such studies in late-onset patients. Rabins *et al.*[33] studied 29 schizophrenia patients with disease onset after the age of 44, and found mean VBR to be greater than for matched normal controls. Naguib and Levy[34] reported similar findings in 43 late paraphrenia patients; there was no correlation between illness duration and ventricular size, and ventricular size did not predict disease outcome at a mean of 3.7 years[35]. In an MRI study, Jeste and Harris[36] confirmed an increase in ventricular size in 20 late-onset schizophrenia patients compared with normals. Again, there was no relationship between illness duration and ventricular size, suggesting that the abnormality preceded disease onset and was not progressive. In an attempt to correlate brain imaging findings with clinical symptomatology, Howard and colleagues[37] reported that ventricular/sulcal enlargement was most dramatically evident in those late paraphrenia patients who did not manifest Schneiderian first-rank symptoms.

The relationship between neuroimaging findings in early- vs. late-onset schizophrenia patients remains a moot point. Pearlson *et al.*[38] compared 11 late-onset with 11 early-onset schizophrenia patients, and found no significant differences between the groups in terms of volume of a number of brain structures. Summarizing these and other such data, Pearlson[39] concluded that "early- and late-onset cases of schizophrenia share common structural ... brain abnormalities". But the significance of these findings is unclear. It seems very unlikely that they have a similar developmental origin to the equivalent abnormalities in early-onset schizophrenia. Indeed, a comparative study of very early (<25 years) and very late-onset (>60 years) schizophrenia patients found that the latter group did not seem prone to those risk factors (e.g. obstetric complications) that have been implicated in the aetiology of the neurodevelopmental form of schizophrenia[40]. Presumably, the ventricular enlargement is of little consequence in its own right, being merely an echo of some undetected cerebral lesion. Burns *et al.*[41] have suggested that there occurs, in late paraphrenia, an "uncoupling" of the normal association between ventricular and cortical size, but the exact mechanism whereby this results in psychotic symptoms is unclear. There is a place for further studies in this area. Specifically, further attempts should be made to find clinical correlates of enlarged ventricles, and to assess predictive value in longer-term follow-up studies. The use of more advanced neuroimaging techniques to search for more specific abnormalities will also be important.

CONCLUSIONS

Many authors consider late-onset schizophrenia to be "a form of schizophrenia, albeit attenuated and modified". One suggestion is that inherent genetic vulnerability, itself insufficient to cause psychosis, acts in concert with environmental factors (social isolation, sensory impairments, non-specific brain atrophy) to precipitate delusional breakdown. Paranoid/schizoid premorbid personality traits might be an expression of such intermediate genetic loading.

Alternatively, the late-onset schizophrenia-like states could be considered as comprising one or more subtypes, relatively distinct from early-onset schizophrenia. For example, Post[14] delineated "paranoid psychosis", "schizophreniform psychosis" and "late schizophrenia"; however, this schema has neither prognostic nor aetiological utility. A more useful approach might be subdivision based on biological parameters that have a bearing on pathogenesis, e.g. the finding of a subgroup of patients with subcortical white-matter changes has important heuristic implications.

Our own view is conditioned by our belief that early-onset schizophrenia is a neurodevelopmental disorder whose origins lie in faulty brain development in foetal or neonatal life[42]. It seems a long bow to draw to suggest that patients with the first manifestation of psychosis in late or very late life have a neurodevelopmental illness. In this context, we consider that those patients currently labelled "late-onset schizophrenia" form a heterogeneous group, some of whom have an illness relating to paranoid personality, some to sensory deprivation, some to late-onset organic change and some to affective illness. A degree of interaction will be expected between these factors. Careful clinical, neuroimaging and, ultimately, pathological examination of such patients will be required to further elucidate these issues.

Brain Imaging in Schizophrenia-like and Paranoid Disorders in Late Life

Robert Howard

Institute of Psychiatry and Maudsley Hospital, London, UK

Two general conclusions can be drawn from the results of brain-imaging investigations of patients with an onset in late life of a schizophrenia-like psychosis. First, the established neuroimaging abnormalities reported in early adult life-onset schizophrenia are also seen in later life-onset patients. Second, imaging has not implicated focal or generalized neurodegenerative abnormalities that can be implicated in psychosis aetiology, as has been the case for late-onset affective disorders.

STRUCTURAL IMAGING

Computed tomography (CT) studies of onset after 45 years[1] and 60 years[2] patients have shown lateral and third ventricle volume enlargement that does not approach the ventriculomegaly seen in Alzheimer's disease. Structural magnetic resonance imaging (MRI) has confirmed these findings, as well as indicating possible reductions in left temporal lobe and superior temporal gyrus volumes[3–5]. MRI studies of patients with so-called "late-life psychosis" have included patients with organic as well as schizophrenia-like psychoses and, not surprisingly, have reported an excess of focal structural abnormalities within deep grey and white matter structures[6]. Similar studies of patients with more rigorously defined late-onset schizophrenia, with exclusion of individuals who are cognitively impaired or have clinical evidence of focal cerebrovascular disease, have found no significant increase in such focal brain lesions compared to age-matched comparison subjects[7,8].

FUNCTIONAL IMAGING

Resting bloodflow abnormalities have been reported with single-photon emission computed tomography (SPECT) in "late-life psychosis", which may include patients with organic psychoses[9]. To date no bloodflow studies using cognitive activation paradigms have been reported in late-onset patients. A single neuroreceptor positron emission tomography study has reported increased binding values for dopamine D2 receptors[3], although age-matched control subjects were not examined for comparison. In a small group of drug-naive onset 60+ patients, we were unable to demonstrate any absolute increase in striatal D2 receptor number compared with elderly controls using SPECT[10]. Hence, the issue as to whether or not neuroreceptor levels are abnormal in late-onset cases mirrors the dispute in the early-onset schizophrenia literature.

Although brain imaging studies to date have supported the concept that early- and late-onset cases of schizophrenia share common structural and neuroreceptor brain abnormalities, more sophisticated future studies may show differences. These may help to settle which of two current hypotheses concerning the aetiopathology of late-onset schizophrenia and very late-onset schizophrenia-like psychosis are most likely to be correct. If schizophrenia arising at any point in life is essentially a unitary condition, then we cannot expect neuroimaging studies of even remarkable sophistication to reveal differences between early- and late-onset cases[11]. If (and the author favours this second hypothesis) the later-onset cases represent a subtle organic phenocopy of schizophrenia, then application of novel imaging methodologies, such as diffusion tensor imaging, which allow high resolution definition of white matter structures *in vivo* should be informative in the next few years.

Although paranoid symptoms are commonly encountered in a range of psychiatric disorders that present to old age psychiatrists, remarkably few epidemiological studies of mood-incongruent paranoid states have been reported compared with cognitive and affective disorders[1]. Because these conditions are comparatively rare, it is difficult to determine their prevalence and incidence accurately. The epidemiological information that we do have on such states that have their onset in later life has come from two sources: studies based upon patients in contact with psychiatric services, and surveys of the elderly general population. Because of the nature of paranoid states, sufferers are unlikely to cooperate with community surveys and are often hidden from contact with psychiatric services. Thus, all the studies reviewed below are likely to represent underestimates of the true prevalence and incidence of these disorders.

PARANOID IDEATION AMONG COMMUNITY-LIVING ELDERLY

In 1173 subjects aged over 64 years in the Epidemiological Catchment Area survey, with a response rate of 85%, generalized persecutory ideation, as assessed on the paranoid scale of the Mini-Mult, was present in 4%[2]. There was a significant excess of unmarried individuals among those with persecutory ideation, but no association with gender or living alone. Other associated features were visual and hearing deficits, cognitive impairment, impaired physical health and disabilities in daily living, together with reduced social and economic resources. Among a community sample of 1420 individuals aged over 75 years, paranoid ideation (defined as recording of paranoid symptoms by both a physician and informant's interview) was found in 6.3%[3]. The prevalence of paranoid ideation in people with cognitive impairment was 12.1%, while it was only 2.6% in those who were cognitively intact. Once the effect of cognitive impairment has been controlled for, the variables significantly associated with paranoid ideation were being divorced, being female, having depressive symptoms, receiving psychotropic drugs, having no friends or visitors, using community care and being an immigrant. In a survey of 935 interviews with individuals aged 70 or over in Canberra and a neighbouring town[4], 65 had at least one psychotic symptom; 22 reported current auditory hallucinations only, 23 delusions only and three hallucinations and delusions: 25 of these individuals had cognitive impairment or dementia. The point prevalence of psychotic symptoms was 5.7% and the significantly associated risk factors, apart from cognitive impairment, were living alone, male gender, limited education, social isolation, poor health and depressive symptoms.

HALLUCINATIONS IN COMMUNITY-LIVING ELDERLY

Data from the Epidemiological Catchment Area study were used to estimate the self-reported age-specific prevalence of hallucinations in a sample of 15 258 individuals of all ages. Patients with dementia were not excluded, and although the prevalence of both auditory and visual hallucinations was highest in young subjects, an increase in auditory and visual hallucinations was found in the elderly, with a rate of visual hallucinations of 40/1000/year in males aged 80+[5].

PSYCHOSIS DIAGNOSED IN COMMUNITY-LIVING ELDERLY

The prevalence of schizophrenia and delusional disorder in those aged 65+ in the community has varied widely from study to study, but on the whole low rates have been found. The Epidemiological Catchment Area survey found a prevalence of schizophrenia of 0.2%[6] and the 6 month prevalence rate of schizophrenia was 0.4–0.6% in a Danish survey[7]. In a sample of 612 elderly Chinese Singaporeans examined using GMS–AGECAT criteria, 0.5% had schizophrenia or paraphrenia diagnoses[8]. From a random sample of 5222 individuals aged 65+, Copeland and colleagues[9] made estimates of the prevalence and incidence of DSM-III-R-defined delusional disorder and schizophrenia. The sample were chosen from the lists of general practitioners' patients and were interviewed by nurses trained in the use of the GMS–AGECAT computerized diagnostic system. The prevalence of DSM-III-R schizophrenia was estimated at 0.12% (95% CI, 0.04–0.25%) and delusional disorder at 0.04% (95% CI, 0.00–0.14%). The minimum incidence of schizophrenia for new cases was 3.0, for new and relapsed cases 45.0, and for delusional disorder 15.6/100 000/year. Two of the five cases of schizophrenia identified in the sample were found to have been first diagnosed before the age of 65.

Principles and Practice of Geriatric Psychiatry, 2nd edn. Edited by J. R. M. Copeland, M. T. Abou-Saleh and D. G. Blazer

STUDIES BASED ON PSYCHIATRIC CONTACTS

From the 1966 official figures from England and Wales for individuals aged over 65 years, Kay[10] calculated annual incidence rates of schizophrenia of 10–15/100 000 for males and 20–25/100 000 for females. The annual incidence of DSM-III-R-defined schizophrenia in the over-65s on the Camberwell Case Register was estimated at 12.6 per 100 000[11]. van Os and colleagues[12] examined the annual incidence rate of late-onset (age 59+) non-affective, non-organic psychosis in 8010 elderly admissions to psychiatric hospitals in The Netherlands and 1777 elderly admissions in the UK. The incidence of psychosis showed a significant increase with age in both countries, the cases rising from around 10/100 000 person-years in the age group 60–65 years to just over 25/100 000 person-years in the 90+ age group. After adjustments for the possible confounding effects of time trend and gender, the linear trend in the association between increasing age and first admission rates corresponded to an 11% increase in incidence with each 5 year increase in age.

COURSE AND COGNITIVE PROGNOSIS

Long-term follow-up of those patients we used to call "late paraphrenics", but should now describe as suffering from "very late-onset schizophrenia-like psychosis"[13], has shown that in the absence of cognitive impairment at the outset, the mortality rate does not differ from expectation and the causes of death in these patients are similar to the general population[14]. When those patients with accompanying organic brain syndromes and associated cognitive impairment are included in follow-up studies, rates of progression to dementia and mortality are, not surprisingly, high[15].

The Fate of Schizophrenia with Advancing Age: Research Findings and Implications for Clinical Care

Robert Howard
Institute of Psychiatry and Maudsley Hospital, London, UK

Although approximately 20% of the long-stay population of psychiatric hospitals in the UK are aged over 65 years[1], and the large-scale closure of mental hospitals that began in the 1950s is nearing completion, old schizophrenic patients and the factors that might influence the success of their move into the community have only recently become the subject of serious study[2]. Ready availability of nursing-home places and a lack of public concern about the potential dangerousness of elderly people with schizophrenia in the community have fostered such disinterest, although the numbers of people involved are enormous: some 200 000 elderly people with schizophrenia have been discharged to nursing homes in the USA[3].

LONG-TERM OUTCOME IN SCHIZOPHRENIA

Enduring positive symptoms of psychosis, cognitive deficits, negative symptoms and adaptive problems may all contribute to long-term disability in schizophrenia. Although some long-term follow-up studies suggest that cognitive and social decline plateau after the age of 40 years and that some symptoms actually improve with increasing age[4–6], many patients experience multiple exacerbations of illness or spend many years in hospital[7]. Although we are traditionally taught that males have a generally worse prognosis in schizophrenia, the situation is complicated. At 2–13 years after initial diagnosis, females do seem to do better[8,9], but their advantage may be lost after 20 years[4,6]. From follow-up studies spanning three decades, Seeman[10] has suggested that males are typically more severely ill in the first 10 years of illness but then improve, while females, after a relatively need-free first decade, show increasing disability over time.

COGNITIVE IMPAIRMENT

The mean Mini-Mental State Examination (MMSE) score in a group of 38 chronic elderly schizophrenic inpatients in one study was 9.6[11]—well within the moderately demented range. Such cognitive deficit does not appear to be specifically linked to a history of brain-damaging treatments, such as leucotomy, insulin coma therapy or lifetime total neuroleptic dosing[7] and cannot be attributed to the appearance of Alzheimer-type neuropathological change, which is rare in the brains of such patients coming to neuropathology[12]. Indeed, in a neuropathological study of 66 patients with schizophrenia, 68% of whom had a history of marked cognitive impairment in life, only 8% had brain changes that satisfied diagnostic criteria for AD[13]. Although cognitive impairment in such patients cannot therefore be attributable to AD, those patients with most severe impairment had significantly more plaques and tangles in their brains than did the unimpaired subjects examined. Severe cognitive impairment is the most important single predictor of poor outcome in chronic schizophrenia[14]. There is debate in the literature regarding whether or not schizophrenic cognitive impairment progresses within chronic illness. Although cross-sectional studies have tended to suggest that cognitive function does not decline over time in schizophrenia[15,16], there is no doubt that cognitive impairment does appear at some point in the illness. Either it is present as a static feature at or soon after illness onset, or it progresses insidiously or in limited subgroups of patients, so that the studies have missed it. This latter point is supported by the results of a large 30-month cognitive follow-up study of 326 chronic schizophrenic patients aged over 65 years[17]. In this study, 30% of patients who had baseline scores in the less impaired range of the Clinical Dementia Rating scale showed a worsening of this score at follow-up to moderate or more severely impaired levels. Only 7% of the sample with lower scores at baseline showed any improvement in functioning. Factors predicting cognitive decline included lower levels of education, older age and more severe positive symptoms. Although the cognitive and functional decline over 30 months demonstrated by this study was convincing and dramatic, it is important to remember that the patients involved were chronically institutionalized, with very adverse illness courses. Middle-aged poor-prognosis schizophrenic patients may also have neuroimaging evidence of progressive ventricular enlargement[18]—further support for the thesis that a subgroup of middle-aged or elderly schizophrenic patients with poorly controlled symptoms are at particular risk of declining cognitive function. Although cognitive deficits have received the most research attention, because they are relatively straightforward to measure reliably and appear to be so predictive of outcome, they represent only a single dimension of disability in chronic schizophrenia. In a study of 102 middle-aged or elderly outpatients with schizophrenia, assessed with the Direct Assessment of Functional Status (a standardized measure of behaviours during performance of simulated daily tasks), patients were significantly more limited than controls on all subscales, except for grooming and eating[19]. Schizophrenic patients were more disabled than outpatients with major depression, but less impaired than those with Alzheimer's disease. Lower levels of formal education, greater severity of extrapyramidal symptoms and cognitive deficits were all associated with lower functional assessment scores.

THE EFFECTS OF INSTITUTIONALIZATION

Since poor long-term outcome in schizophrenia is associated with long institutionalization and cognitive impairments, could the deficits be a consequence of a non-stimulating psychiatric hospital environment or overtreatment with medication? One simple way to examine the possible causal relationship between these factors has involved comparing the cognitive and adaptive functioning deficits in groups of elderly schizophrenic patients cared for in different types of institutions in widely differing parts of the world. In a cross-national study of cognitive impairment in poor-outcome geriatric patients with schizophrenia[20] in London and New York, remarkable similarities in cognitive dysfunction between the US and UK patients were found, despite differences in the structure of institutional care provided. Mean MMSE scores in New York were 10.5 and in London 10.6. When the patients in the two centres were investigated with an adaptive functioning scale, however, differences emerged which were probably related to institutional differences. American patients were more impaired in social initiation, but less impaired in social competence and personal hygiene, than their English counterparts.

WHERE ARE PATIENTS BEST LOOKED AFTER?

It is probably unsafe to make generalized assertions about the ways in which the needs of elderly schizophrenic patients are best met because they are a heterogeneous group in terms of enduring psychotic symptoms, cognitive and adaptive deficits and family or other social support. In a cross-sectional study of 97 chronically hospitalized schizophrenic patients, 37 chronic schizophrenic residents in nursing homes and 31 acutely admitted geriatric patients with schizophrenia, patients in each of these groups had very different patterns of symptoms and impairments[21]. Whilst differences in positive and negative schizophrenic symptoms were small, nursing-home residents had the most severe adaptive deficits. Prospective studies of chronic schizophrenic patients successfully discharged to nursing homes, compared with those who are retained in long-term psychiatric care, have shown that it is not cognitive or adaptive deficits that prevent discharge but continuing belligerence and hostility[22]. Just as it appears unwise to generalize about the care needs of patients, it is rash to assume that all nursing homes or long-stay psychiatric facilities are the same. When 159 long-term schizophrenic inpatients within Veterans Administration hospitals were allocated to either a community nursing home, a Veterans Administration nursing home or another long-stay psychiatric ward, or allowed to remain on their original ward, at 12 months the patients with the best outcomes were those who had been transferred to another long-stay ward. The worst outcomes were seen in those who had been discharged to community nursing homes[23,24]. Rather than the location of care, particular features of the quality of care were the factors most strongly associated with good outcome. Staffing characteristics, e.g. the staff:patient ratio and the rate of staff turnover, together with the mean functional ability of fellow residents, were significantly linked to outcome. A similar study from the UK came to superficially conflicting conclusions. Elderly long-stay schizophrenic patients transferred to nursing homes showed slower functional decline over the next 2–3 years than those who remained on the wards[25]. The important difference from the situation in the Veterans Administration study was that in the UK study staff–patient contact was greater in community facilities than on the long-stay wards and this contributed to better outcome. Studies such as those reviewed above examine only the grosser disabilities and deficits of elderly schizophrenic patients and the few published investigations of quality of life give a rather depressing insight into exactly what the lives of these people are like. In a 10 year follow-up of 40 older patients with schizophrenia, overall subjective quality-of-life ratings did not improve from the low levels seen at the beginning of the study[26]. Ratings on a small number of items (contacts, inner experiences and knowledge/education) had improved slightly, but the reasons for these improvements were just as likely to be that patients had downgraded their expectations as that they were interacting more successfully with their environment or that housekeeping services received had improved.

MORTALITY IN CHRONIC SCHIZOPHRENIA

Excess mortality among patients with schizophrenia is a consistent and accepted research finding that cannot be fully explained by the observation that 10% of patients will kill themselves[27]. In a prospective study of 88 schizophrenic patients with a mean age of 62.6 years at study commencement, 39 had died after 10 years' follow-up—none through suicide[28]. The relative risk of death among the patients was 1.33 (95% CI, 1.01–1.65). Six variables, some of which have important clinical implications, affected independent prediction of reduced survival and these were: increasing age; male gender; the edentulous state; time since most recent neuroleptic withdrawal; maximum number of antipsychotics given concurrently; and the absence of anticholinergic treatment.

IMPLICATIONS FOR CLINICAL CARE

Since elderly patients with chronic schizophrenia have high levels of disability and dependence upon caring services, their apparent invisibility to mental health policy makers must largely be attributable to ageist assumptions that they should not expect much more than basic nursing home provision, and to a lack of general public concern about the safety of placing elderly (and therefore "low-risk") psychotic patients in the community. They also represent a group of patients who are poorly served by specialist psychiatric services. Sometimes rather grandly termed "graduates" because they are alumni of mental health services set up for younger patients, it is often not clear whether they have become the responsibility of local old age psychiatrists or whether they should continue to be looked after by the general adult psychiatry teams with whom they have been in contact. In a call to arms to all mental health professionals who may be involved in the care of these patients, Rodriguez-Ferrer and Vassilas have set out four objectives of importance in the establishment of a seamless and ideal service. First, general practitioners should be central in the coordination of service provision and should be involved in the assessment of physical needs, as well as psychiatric ones. Second, the organization and delivery of specialist mental health services should take into account the fact that, in the future, the majority of these patients will live in residential and nursing homes. Third, purchasers of mental health services need to be aware of the effects of the quality of the physical and staffing environment of residential and nursing homes on patient functioning. Finally, services should maintain clarity at all times as to exactly which agencies (psychiatric, social, voluntary) have responsibility for each individual's care. Now that we have an agenda for the management of this hitherto-neglected group, together with novel antipsychotic agents that are less likely to induce movement disorders and may even improve cognitive function[29], this really does represent a clinical population for whom recent research has positive implications. The most recent indications are that deinstitutionalization has been, on the whole, a modest success. At the end of a 5 year follow-up of 670 elderly

chronic patients (80% of whom had schizophrenia), 89.6% were still living in the community and only one-third had required any kind of hospital readmission[30].

Rehabilitation and Long-term Management

Robert Pugh
St Luke's–Woodside Hospital, London, UK

THE LONG-TERM OUTCOME OF SCHIZOPHRENIA

Schizophrenia has been conventionally considered to be a disorder with a poor long-term prognosis. The concept of schizophrenia as a disorder with a poor prognosis was reflected by DSM-III[1], where features included a failure to return to premorbid functioning, recurrent acute exacerbation with increasing residual impairment between episodes, continued symptoms, unemployment, social isolation and an inability for self-care. DSM-IV[2] included a revised view of schizophrenia, stating that most studies of the outcome of schizophrenia suggest that the course may be variable, with some individuals displaying exacerbation and remission, whereas others remain chronically ill.

The pessimistic views on outcome had mainly been formed from the early longitudinal studies reported by Kraepelin[3] and Eugen Bleuler[4]. In the course of his work, Kraepelin became pessimistic about the outcome of dementia praecox, reporting that fewer than 5% of patients sustained a lasting recovery. When Eugen Bleuler originally described the concept of schizophrenia, an essential component of the diagnosis was that patients were not able to regain their premorbid abilities. These early studies have had a major effect on our concept of schizophrenia. Indeed, many psychiatrists[5,6] considered that if a patient makes a good recovery, then the validity of the diagnosis of schizophrenia may be in question. These views still persist and have had a major effect on service planning for people suffering from schizophrenia and their medical management. Five, large, long-term studies of schizophrenia patients have produced very different results from those of Kraepelin and Bleuler and have effectively challenged this view.

Harding *et al.*[7,8] carried out a 32 year follow-up study of a rehabilitation programme of comprehensive rehabilitation and community placement for those "backward" patients who had not improved sufficiently following the introduction of chlorpromazine. A total of 269 patients who were considered to be amongst the most severely disabled and chronically mentally ill in the hospital were referred to the programme. After an average of 32 years, 178 were still alive and were interviewed again; 71 patients had died and in these cases the family were interviewed; 13 other patients were still alive but refused participation; and the remaining seven could not be located. A battery of interview instruments described as the Vermont Community Questionnaire was used to evaluate outcome. Evidence of good inter-rater reliability and face and construct validity for the questionnaires are presented in their paper. The patients were rediagnosed using DSM-III classification retrospectively: 188 of the original subjects were considered to have met the DSM-III criteria for schizophrenia. The results showed that the long-term outcome was mixed, with many patients demonstrating various degrees of productivity, social involvements and competent functioning; 68% of the patients displayed neither positive nor negative symptoms of schizophrenia at follow-up and 45% of the sample displayed no psychiatric symptoms at all; 82% of patients had not been in hospital in the last year; 61% met with friends every week or two; 68% had one or more moderately/very close friends; 40% had been employed in the past year; 81% were rated as being able to meet basic needs; and 73% were felt to lead a moderate to very full life. The study also includes an assessment of income; 77% of the sample were assessed on the Community Care Schedule as having an adequate income. The schedule's definition of "adequate" was that "the amount of money received will cover the subject's basic needs comfortably". Four other studies report similar findings.

Manfred Bleuler[9] described a follow-up study of 208 patients who met his own and Eugen Bleuler's diagnostic criteria for schizophrenia, and reported a significant improvement in 53% at a 23 year follow-up.

Huber *et al.*[10] described the largest study, following up 502 patients over an average of 22.4 years, using the diagnostic criteria of E. and M. Bleuler[4,9,11] and Schneider[12]; 53% showed significant or total improvement.

Ciompi and Muller[13] followed up 289 patients admitted before the age of 65 who were over 65 by 1963. The mean length of follow-up was 36.9 years. The diagnostic criteria of E. and M. Bleuler were used; again, over 50% (57%) of patients showed significant improvement.

Tsuang *et al.*[14] followed 186 patients admitted to Iowa State Hospital between 1934 and 1944 for a period of 35 years. In this study, 46% showed significant improvement.

The results of these studies challenge the prevailing concept of outcome in schizophrenia and support the concept of heterogeneity of outcome. Together, these studies found that between one-half and two-thirds of more than 1300 patients studied for a period in excess of 20 years achieved recovery or significant improvement. This is not to deny the fact that many patients do not show an improvement over the years and require continuing medical and social support, but it clearly suggests that it is erroneous to view deterioration as an inevitable outcome.

The differences between these studies and those of Kraepelin and Bleuler have been attributed to sampling biases. The criticism has been that both Kraepelin and Bleuler chose samples of patients who were admitted to hospital for long-term care. In addition to this, Kraepelin's studies probably included patients with tertiary syphilis and other organic disorders for which tests were unavailable at the time. Certainly, Eugen Bleuler's son, Manfred Bleuler, attributed his father's pessimism about the outcome of schizophrenia to this bias.

ENVIRONMENTAL, SOCIAL AND CULTURAL FACTORS AND OUTCOME OF SCHIZOPHRENIA

There is evidence that environmental factors play a major part in the outcome of schizophrenia, although this is clearly not as marked as was first claimed in the early descriptions of institutionalization by Barton[15] and Goffman[16]. They considered that the disabilities of long-stay patients were primarily due to the psychiatric institutions in which they lived. In a major study of these institutions, Wing[17] studied the outcome of patients who were managed in three hospitals with very different policies of care. He concluded that institutionalization had contributed significantly to the patients' disabilities.

The influence of environment and culture was also illustrated by the WHO international pilot study of schizophrenia[18], in which 1202 patients diagnosed as having schizophrenia in 10 different countries were followed up over a 2 year period. The heterogeneity of outcome was again underlined, but patients suffering from schizophrenia in the developing countries had a better outcome than those in the developed countries. The report concluded that the diagnosis of schizophrenia alone did not provide sufficient grounds for a firm statement about the patient's likely pattern or course, probability of relapses and admissions, or the degree of social impairment in the future.

Similar findings emerge from a 5 year follow-up study of patients living in the peasant society of Sri Lanka, described by Waxler[19]. She concluded that in Western society, expectation and a belief about mental illness and the process by which treatment is provided alienate patients suffering from schizophrenia from their normal roles, and thus prolong illness. In contrast, the beliefs and practices in non-industrial societies encourage a quick return to normality.

THE ROLE OF REHABILITATION

Although the recent outcome studies have shown that the prognosis of schizophrenia is not as poor as had previously been considered, it is also clear that outcome is mixed, with some patients showing no improvement and remaining severely disabled. Continuing care services for people suffering from schizophrenia should aim to reduce these disabilities wherever possible and to meet the needs of those who remain severely disabled into old age.

The care of patients with schizophrenia has moved from long-term hospital to care in the community. This international change occurred with very little contemporary evidence to support it. However, the controlled studies that exist[20,21] demonstrate that patients treated in the community did not experience increases in homelessness, mortality or suicide and did not need excessive readmissions to hospital. Importantly, patients taking part in these studies preferred treatment outside hospital.

Intercultural studies would support the concept that environmental factors can have an effect on outcome. However, although one would expect that the socioenvironmental factors involved in community care would improve the prognosis, this has been very difficult to demonstrate in practice. Wing's Three Hospital Study is one of the few papers that supports this view. There is little evidence that psychiatric symptomatology or psychosocial function improve when patients are treated in the community.

In the UK the view that all patients with schizophrenia can have long-term care in the community has been revised, and there is provision for 24 hour nursing care[22]. Treiman[23] demonstrated that this care can be successful in reducing severely disrupted behaviours. However, this group of patients are different from the long-stay hospital population. They are younger, suffer from more psychotic symptoms and often have multiple problems, such as cognitive deficits, substance misuse and violence. Their self-care skills are often intact.

CHANGES IN REHABILITATION

One problem in interpreting these studies is that the term "rehabilitation" may mean very different things to different people, and indeed, in recent years the term "rehabilitation" has sometimes even become synonymous with discharge from hospital. This use of the word is misleading. Bennett[24] considered that the goal of rehabilitation was to enable the individual "to make the best use of his residual abilities in order to function at an optimum level in as normal a social context as possible". He introduced the concept of rehabilitation as a continuous and recursive process, applicable in many service settings, which could be independent of the discharge process. He considered the interaction between the individual and the environment to be particularly important. Rehabilitation should entail both working with patients to enhance their confidence and coping skills and the provision of such "prosthetic environments" and social, emotional and material support as may be necessary to maintain their optimal level.

The concept of helping a patient to cope with his/her disability is central to rehabilitation and forms the basis of cognitive-behavioural therapy for schizophrenia[25]. Patients may deny that they are unwell and this may make engaging them in treatment difficult. It is important to approach their problems from their point of view and work with them to reduce the problems they perceive as important. Education about their illness and medication may be helpful. It is also helpful to discuss exacerbating factors, such as stress and substance misuse. Discussion of early signs of relapse, such as unusual behaviour or prodromal symptoms, may enable patients to prevent a serious relapse. The involvement of family and friends is often helpful. If assessment of risk reveals a substantial risk to the patient or others, then patients should be engaged in the process of reducing the risk.

The Royal College of Psychiatrists report on Rehabilitation emphasized the importance of primary, secondary and tertiary disability[26]. The primary disabilities are emotional, cognitive, motivational and behavioural dysfunction. Secondary handicaps include loss of self-esteem and confidence, social withdrawal and loss of social roles and networks. Unemployment, homelessness, poverty and stigmatization are the tertiary handicaps. Often patients' main concerns are about the secondary and tertiary problems and it is important to address these to achieve an effective treatment plan.

Deegan[27] has described how Mental Health Service users emphasize the importance for them of feeling "in the driver's seat"—empowerment. She uses the word "recovery" rather than "rehabilitation", highlighting the fact that patients recover and professionals rehabilitate. She describes the importance of people becoming experts in their own self-care.

THE PRACTICE OF REHABILITATION

Rehabilitation is based on assessment, development of treatment plans and monitoring. In the UK this forms the basis of the care programme approach. The assessments are based on patients' abilities and difficulties in a wide range of areas. These should include the following.

- *Psychiatric illness:* positive and negative symptoms; insight; compliance with medication; self-medication ability.

- *Physical illness:* specific problems, e.g. diabetes, heart disease; eyesight, hearing and dental problems; preventative medicine, e.g. blood pressure monitoring, breast examination.
- *Education:* literacy and numeracy.
- *Daily living skills:* personal hygiene; laundry skills; budgeting; shopping; cooking; use of public facilities; road safety.
- *Family and social contact:* contact with family; expressed emotion; social networks.
- *Day activities:* work; day hospital; day centre.
- *Financial:* welfare rights, Court of Protection.
- *Accommodation:* patients' wishes; needs based on abilities and difficulties.
- *Risk assessment:* assessment of risk to self and others, including children.

It is often difficult to collect all of the above information and it is important to set a date for an initial review, when the information that has been collected by that time is gathered together. The purpose of the initial review is to appraise the patients' strengths and difficulties and to decide what further information needs to be obtained. Preliminary treatment plans and goals should also be set at this stage. A review of medication, including the use of clozapine for treatment-resistant psychosis[28] and the possible use of cognitive-behavioural therapy[25] and family interventions[29] should be explored.

It is important to have a clear system for reviews, and each patient population or treatment environment requires different systems to be developed, but the essential areas that need to be covered remain the same. Within a district or service it is often helpful to standardize the order of the areas (or headings) in which the assessments are made, so that assessments made in one setting can be easily understood by other teams working in other settings. This leads to improved liaison throughout the service and in particular helps communication between the community and the hospital.

An important part of an initial review is to decide on the order in which problems may be tackled. Sometimes the most important problems are worked on first but on other occasions it may be an idea to start with an easy problem to enable the patient to develop some self-confidence. It is important to set and record practical attainable goals.

Sometimes the review forms or care plan forms that are developed automatically tag the assessment of all strengths and difficulties with treatment plans and goals. This practice can lead to difficulties, as many patients have a large number of problems and in practice only three or four treatment plans can be followed at one time.

The other two vital components of a review are to identify individual staff who have responsibility for components of care and to set a date for a further review when new information on abilities and difficulties can be discussed and the treatment plans and goals evaluated. It is helpful to have patients involved in their treatment programme and many review forms have a space for the patient's signature on them, which assists patient involvement.

RATING SCALES IN REHABILITATION

Although there is no alternative to thorough individual assessments, standardized rating scales can be useful. They are used for the planning of services, the coarse screening of populations to draw up short lists of long-stay patients who may benefit from more intensive assessment of resettlement potential, and for obtaining a quantified assessment of a patient's progress. There are many scales available for assessments in rehabilitation, but few of these have been subjected to investigations of their reliability and validity. The REHAB: Rehabilitation Evaluation[30] is an exception to this and is probably the most widely used scale in the UK at present. It is a scale that has been specifically designed for use with long-stay patients and was developed during the course of a 7 year research study. On the basis of behaviour, over 1 week raters complete 23 items in total; seven three-point response scales indicate the frequency of occurrence of difficult or embarrassing behaviours and produce a deviant behaviour score (DV); aspects of social and everyday behaviour are rated in 16 items, each using a visual analogue response format, with written descriptions at each end on which the rater makes a mark that is scored 0–9 using a template. These scores are aggregated to yield the general behaviour score (GB), which can be used to categorize patients as "discharge potential", "moderate handicap" or "severe handicap". There are also five scale scores—social activity, speech disturbance, speech skills, self-care and community skills. The Handbook for the scale is particularly useful, in that it enables one to compare the patient's scores with scores in other populations, so that one can estimate the proportion of people with similar scores in the hospital or the community. Sensitivity to change has also been demonstrated. Provided that raters are properly trained, good reliability levels can be achieved and, once training has been undertaken, the scale itself is brief and easy to complete and score.

CONCLUSION

In conclusion, long-term outcome studies have demonstrated that schizophrenia has a much more heterogeneous outcome than had previously been understood, with many patients making substantial improvements over the years. The effects of environment on outcome are complex and require further long-term evaluation. The aim of rehabilitation is to enable patients to cope with their illness and make the most of their lives, by reducing symptoms and increasing abilities whenever possible and by providing supportive services to match individual need. It is important to see problems from the patients' point of view. In practice this is achieved through a series of reviews which are a focus for assessment, goal planning and evaluation.

Treatment of Late-onset Psychotic Disorders

Elsa M. Zayas and George T. Grossberg
St Louis University, St Louis, MO, USA

As the world population ages, a greater proportion of the population will be over the age of 65. Psychopathology can present in various ways in the elderly. Psychoses, as defined in DSM-IV, consist of "delusions or prominent hallucinations occurring in the absence of insight into their pathological nature"[1]. Hallucinations can be visual, auditory, tactile and/or olfactory in nature. Delusions or falsely-held beliefs are at times very difficult to distinguish from reality. They may require corroboration from caregivers to authenticate their psychotic nature.

Psychotic disorders can present in the elderly as either chronic or acute conditions. The disorders can include early- and late-onset schizophrenia, schizoaffective disorders, delusional disorder, mood disorders with psychotic symptoms, delirium and dementias with psychosis. Furthermore, the etiology of psychosis can be the result of medical conditions, such as Parkinson's disease or neoplasms, as well as drugs or other substances (Table 95.1).

Table 95.1 Psychotic disorders manifested in the elderly

Schizophrenia
Late-onset
Aging patients with early onset
Schizoaffective disorder

Delusional disorder
Dementia with psychotic symptoms
Alzheimer's dementia
Vascular dementia
Lewy body dementia
Mixed dementias
Delirium
Psychoses due to a general medical condition
Psychoses due to a substance
Mood disorders with psychotic symptoms

EPIDEMIOLOGY

The geriatric data from the Epidemiologic Catchment Area study showed, at three sites, a 6 month prevalence for schizophrenia and schizophreniform disorders of 0.2–0.9%; cognitive impairment, including organic psychosis, was 16.8–23%[2]. Reported prevalences of psychotic disorders in a nursing home population was 10% and in a community-based sample in Sweden 4.7%[3,4]. Patients with Alzheimer's disease may also exhibit psychotic symptoms, with reported prevalences as high as 63%[5].

Patients with late-onset schizophrenia (LOS) present with their psychotic symptoms after the age of 45. LOS tend to be predominantly women, and have better premorbid functioning compared to younger schizophrenics[6]. Women with late-onset compared to early-onset schizophrenia tend to have more severe positive symptoms and fewer negative symptoms when compared to men with late onset of the disorder[7]. Women also tend to have less social withdrawal, better premorbid functioning and a gradual decline in functioning[8,9]. Patients with late-onset schizophrenia tend to have less affect flattening and formal thought disorder[6]. Aging patients who suffer from schizophrenia may have less intensity of their symptoms[10].

Delusional disorders are defined as non-bizarre falsely-held beliefs with minimal hallucinations[1]. Delusional disorders often have their onset in mid- or late life[11] and tend to affect men earlier than women[12]. Low socioeconomic status, immigration, hearing loss and bedfast status are some of the risk factors for developing a delusional disorder[13–16]. Psychotic symptoms seen in dementias can consist of hallucinations or delusions.

NEUROCHEMICAL HYPOTHESIS

The dopamine hypothesis of schizophrenia associates an increase in the activity of dopamine in various cortical areas that are concerned with positive, negative and cognitive symptoms of schizophrenia, as well as side effects seen with the use of neuroleptics. An increase in the level of dopamine activity in the mesolimbic pathways of the brain would be associated with the psychotic symptoms seen, i.e. hallucinations and delusions. Blockade in activity at the mesocortical pathway would be associated with cognitive symptoms and may account for worsening of the negative symptoms seen with conventional antipsychotics. Blockade of dopamine at the tubuloinfundibular tract is associated with increases in prolactin levels, a troublesome side effect which, in younger patients, may lead to non-compliance and discontinuation of treatment.

DIFFERENTIAL DIAGNOSIS

Prior to initiating treatment, it is essential to conduct a biopsychosocial evaluation of the patient. Delirium is often the cause of an acute onset of psychotic symptoms in the elderly and must be foremost in one's differential assessment. Delirium, defined as an acute mental status change with waxing and waning of the levels of consciousness, often presents with hallucinations, predominantly visual, as well as delusions.

Medical conditions in the elderly that can cause delirium include: infection (frequently urinary tract infections); metabolic disorders (thyroid disease, diabetes); electrolyte imbalances; pain;

Table 95.2 Differential diagnosis of psychotic disorders in the elderly

Impaction

acute events, such as myocardial infarctions, strokes, transient ischemic attacks; and exacerbation of chronic conditions, such as chronic obstructive pulmonary disease. Furthermore, medications are frequently part of, if not the underlying etiological cause of, delirium. Medications may contribute as a result of their side-effects profile, toxicity or mechanism of action. Inquiries should be made about the use of other substances, including alcohol or illegal drugs. Corticosteroids, digoxin, anticholinergic drugs and dopaminergic agents are just some of the medications that may be implicated.

The elderly are very sensitive to the side effects of medications, especially to the anticholinergic side effects of drugs. Many medications have anticholinergic side effects, including many antipsychotics, both typical and atypical. The untoward peripheral anticholinergic effects of dry mouth, constipation, urinary retention and dry eyes are troublesome to the elderly and may further aggravate pre-existing physical conditions. Untoward central effects of these medications include the worsening of confusion and cognitive functioning.

TREATMENT OF PSYCHOSIS

One should keep in mind when treating the elderly the old axiom of ''do no harm''. The risk:benefit ratio of all treatments prescribed to elderly patients must always be assessed. When choosing an antipsychotic, one should take into account treatment history and susceptibility to potential side effects, as well as family history and familial response to medications. An important principle to apply when initiating treatment is to ''start low and go slow''. Treatment should be initiated with doses of half to one-third adult starting dose, remembering that most elderly patients with psychotic symptoms require much lower doses than younger patients.

Age-related bodily changes affect the pharmacokinetics of neuroleptics in the elderly. Absorption of medications may be altered by changes in gastric acidity and emptying and changes in blood flow. Age changes the body's composition, causing an increase in body fat with an associated decrease in lean body mass and total body water. In addition, there are decreases in liver mass and blood flow and changes in renal blood flow and function. All these changes affect the absorption, metabolism, distribution and clearance of neuroleptics.

The phenothiazides are lipophilic substances, well absorbed, with an extensive first-pass metabolism in the liver. In the elderly, as a result of the increase in total body fat, there is an increase in the volume of distribution of drugs. This leads to an increased half-life for those substances that are lipophilic. Thus, the elderly should be given lower doses of lipophilic drugs.

Neuroleptics are the treatment of choice for psychosis. They have recently been divided into typical (conventional) and atypical antipsychotics, based on their capacity to treat the positive and negative symptoms of schizophrenia as well as their potential to cause neurological side effects. All antipsychotics have the same level of efficacy. It may be relevant to recall that 100 mg chlorpromazine is equivalent to 1 mg haloperidol and 0.5 mg risperidone.

Typical or ''conventional'' antipsychotics can be divided into groups, based on their potency—high, intermediate and low potency. High-potency antipsychotics include haloperidol, fluphenazine and loxapine. High-potency neuroleptics have greater affinity for the dopamine receptors and less affinity for the muscarinic and α-receptors. High-potency neuroleptics are more likely to be associated with a higher incidence of extrapyramidal symptoms, akathisia, acute dyskinesia and parkinsonism, thus limiting their use in the elderly. Intermediate potency neuroleptics include perphenazine, loxapine and molidone. The atypical neuroleptics are clozapine, risperidone, olanzapine, quetiapine and ziprasidone. Low-potency antipsychotics, such as thioridazine and chlorpromazine, have a higher affinity for muscarinic, histaminic and α-adrenergic receptors and furthermore are more likely to produce increased sedation, orthostatic hypotension and anticholinergic side effects. They should be prescribed with caution in the elderly.

Limitations of Typical Neuroleptics in Geriatrics

Typical antipsychotics block various receptors that have the potential to cause side effects which can limit their use in the elderly. Dopaminergic blockade is associated with acute and long-term neurological side effects. Acute neurological side effects are extrapyramidal side effects (EPS), which include parkinsonism (resting tremors, rigidity, bradykinesia and gait disturbances), akathisia and dystonias and long-term effects of tardive dyskinesia, as well as the potential for neuroleptic malignant syndrome (NMS). Histaminergic blockade is associated with sedation and weight gain. Their quinidine-like cardiac effects are associated with the potential for arrhythmias. α-Adrenergic blockade leads to orthostatic hypotension. In addition, the muscarinic blockade leads to anticholinergic side effects.

Neuroleptic induced parkinsonism (NIP) is a potential concern with the use of neuroleptics in the elderly. The reported prevalence of NIP in patients aged over 60 on neuroleptics is 50%[17]. One study that looked at the use of low-dose neuroleptics and the incidence of NIP in the elderly found that 32% of patients developed NIP on an average daily dose of 43 mg chlorpromazine[17]. In addition, the risk factors contributing to the incidence of NIP were older age, instrumental tremor at baseline, EPS, the type of neuroleptic administered and the severity of dementia[17,18]. Parkinsonism can increase the risk of dependency, falls and fractures[19]. These often troublesome side effects can be treated either by reducing the neuroleptic dose, switching to an atypical agent, or using anticholinergics such as benztropine or trihexyphenidyl. Care needs to be taken when using antiparkinsonian medications in the elderly, who are very sensitive to the anticholinergic side effects.

Akathisia is another neuroleptic side effect that can be difficult to address. Akathisia is characterized by increased restlessness and psychomotor activity, with an inability to sit still. Akathisia is

Table 95.3 Medications/substances associated with delirium

Anticholinergics
Benzodiazepine withdrawal
Alcohol withdrawal
Alcohol intoxication

often mistaken for worsening of the psychotic symptoms, leading one to erroneously increase the neuroleptic dose, when actually lowering the dose may address this troublesome side effect. In addition, akathisia can be treated with benzodiazepines and/or β-blockers.

Tardive dyskinesia (TD) is a potentially irreversible abnormal involuntary choreiform movement disorder. In the elderly, the 3 year cumulative incidence of severe TDs was found to be 2.5% after 1 year, 12.1% after 2 years and 22.9% after 3 years[20]. Another study reported the cumulative rates for TD to be 25% after 1 year, 35% after 2 years and 53% after 3 years[21]. Factors that were predictive of TD included higher daily dose at study entry, greater cumulative amounts of prescribed neuroleptics, greater severity of worsening negative symptoms, and the presence of early EPS[21,22]. Caution should be used when administering conventional neuroleptics in the elderly and they should only be prescribed when necessary and at the minimal effective dose[20].

Neuroleptic malignant syndrome (NMS) is a serious side effect with the potential to be lethal. NMS presents with symptoms of muscle rigidity, fever, autonomic instability, fluctuating levels of consciousness and elevations in CPK and white blood cell counts. NMS can be seen with the use of all neuroleptics, including the atypical[23].

The potential cardiovascular effects of these drugs include orthostatic hypotension and QRS prolongation, leading to an increased risk for torsade de pointe. Orthostasis is of especial concern in the elderly who, due to physiological changes, are already at increased risk. In addition, in those patients who are already suffering from orthostasis or who are being prescribed medications known to have pressure-lowering effects, low-potency neuroleptics should be avoided. Orthostatic hypotension places the elderly at increased risk of falls, leading to increased morbidity and mortality.

The anticholinergic effects of these drugs can have both troubling and undesired peripheral and central effects. Peripheral side effects include dry mouth and eyes, blurred vision, constipation, and urinary retention, which is of especial concern in males who have prostatic hypertrophy. Central effects include worsening of cognition, confusion and/or delirium[3,24]. One should be aware that the atypical antipsychotics clozapine and olanzapine also have anticholinergic side effects.

An additional side effect of concern with the use of antipsychotics is photosensitivity in those patients who are on chlorpromazine. Patients may experience irreversible degenerative pigmentation retinopathy, caused by doses of thioridazine greater than 800 mg/day. Weight gain is of especial concern in those patients with an obesity problem or who are known to gain weight easily on medications. Weight gain can be seen with the use of both conventional and atypical antipsychotics.

Table 95.4 Recommended doses in the elderly

Drug	Initial dose	Maximum dose
Clozapine	6.25 mg/day	50–100 ng/day
Risperidone	0.25–0.50 mg/day	2 mg/day
Olanzapine	2.5 mg/day	5–10 mg/day
Quetiapine	25 mg/day	100–150 mg/day
Ziprasidone	20 mg/day	80–160 mg/day

Atypical Antipsychotics

Atypical antipsychotics are so defined because they are effective at treating both the positive and the negative symptoms of schizophrenia, while having a lower incidence of extrapyramidal symptoms and tardive dyskinesia. FDA-approved atypical antipsychotics are clozapine, risperidone, olanzapine, quetiapine and ziprasidone.

Clozapine

Clozapine was the first atypical antipsychotic approved for use in the USA. Compared to typical neuroleptics, it has a higher affinity for the dopamine D2 receptor, being more selective for the mesolimbic and mesocortical pathways. Clozapine continues to have a favorable neurological side-effect profile but is reported to have the following untoward effects: drowsiness, sedation, hypersalivation, tachycardia, dizziness, constipation, nausea and vomiting, the most concerning being agranulocytosis and seizures. It is recommended that clozapine treatment should be initiated only after a patient has failed two trials with conventional antipsychotics. In a double placebo-controlled study of six patients, clozapine was found to have similar efficacy as in younger patients. Although it was felt to be fairly safe in the elderly, the most frequent side effects were sedation, confusion and agranulocytosis[25].

Concern exists that the elderly may be at greater risk for agranulocytosis. In an Australian elderly study, the occurrence of agranulocytosis was found to be 4% compared to 0.25% in younger patients[25]. Increased sedation, hypersalivation, bradycardia, postural hypotension and delirium are frequent side effects reported in the elderly with the use of clozapine[26–28]. Another potential side effect is weight gain. One author found that 75% of the patients prescribed clozapine had gained an average of 7.5 kg[29]. The potential for agranulocytosis requires constant monitoring of blood, which may be difficult and costly in the elderly. Clozapine was tolerated as well as chlorpromazine in one study. In one open label report in 300 older adults, the discontinuation rate for clozapine was 43% and agranulocytosis occurred in two non-fatal cases[30].

Clozapine should be considered once a patient has failed two trials of conventional neuroleptics. When prescribing clozapine, it is prudent to initiate treatment with a dose of 6.25 mg/day, followed by weekly titration of 6.25 mg/day until a therapeutic effect is achieved and/or side effects develop[13,31]. Daily doses may range from 6.25 to 400 mg[31]. Clozapine should be initiated slowly and titrated slowly. Chengappa[26] has reported that the rapid titration of this drug can lead to drug intolerance and poor response.

Risperidone

Risperidone, a serotonin–dopamine antagonist, is an atypical antipsychotic that is a benzisoxasole derivative[32]. Risperidone has been found to be effective for the treatment of both positive and negative symptoms of schizophrenia, with minimal EPS. Risperidone has been studied extensively in the elderly[33,34]. It is a potent antagonist of the 5-HT receptor and less so of D2, with α-receptor blocking. In addition, it has minimal histaminergic blockade and practically no affinity for cholinergic receptors[35].

Side effects seen with this drug include orthostatic hypotension, sedation, fatigue and palpitations. Risperidone has dose-dependent incidence of EPS and TD. The incidence of sedation is in the range 6–15%[36–38]. There are no cardiac or laboratory abnormalities associated with this drug. Hypotension can be seen and should be carefully monitored in patients with pre-existing hypotension or who are on medications that have this effect. The 1 year incidence of TD seen in a large sample of elderly patients treated with risperidone was 2.6%[39].

Risperidone is the atypical antipsychotic most widely studied in the elderly. Most studies have favored the use of lower doses, finding them to be efficacious. In a study of patients who were diagnosed with dementia with behavioral disturbances, risperidone was found to be effective at doses of 1 mg/day; more adverse events were seen at doses of 2 mg/day[34]. These authors recommended the use of a serotonin–dopamine agonist when treating elderly patients with psychotic symptoms[34]. In a population of American veterans the average dose of risperidone was 3.6 mg/day compared to an average olanzapine dose of 10.2 mg/day[40] that EPS were reduced from baseline.

Risperidone has been found to be effective in treating both the negative and positive symptoms in patients with the diagnosis of schizophrenia and schizoaffective disorders. In a prospective open-label, 12 week study of 103 elderly patients who were diagnosed with schizophrenia or schizoaffective disorders the mean dose was 2.4 mg/day. An overall improvement of 45% was seen for both PANNS and CG[37]. The most frequently reported adverse events were dizziness, insomnia, agitation, somnolence, constipation and EPS. The authors concluded that risperidone was safe in this population but that doses should not be lower than 3 mg/day. Various authors have found risperidone to be a safe and efficacious treatment in this population[33,37,38]. In the medically ill elderly with psychotic symptoms, risperidone is also an effective and safe treatment. It does demonstrate dose-dependent EPS[37,41]. Risperidone treatment should be initiated at low doses (0.25 mg/day) and slowly titrated to a target dose of 1.5 mg/day for patients with dementia with psychotic symptoms. In elderly patients with psychosis, the optimal dose should be 2 mg/day. Risperidone in the elderly is an effective safe first-line treatment of psychosis.

Olanzapine

Olanzapine is a thienobenzodiazepine analog with an *in vitro* receptor affinity profile similar to clozapine. It is considered to be an atypical antipsychotic, as it is more effective than haloperidol in the treatment of both positive and negative symptoms of schizophrenia with minimal EPS[42]. Olanzapine affects the dopamine D1 and D4 receptors and the serotonin 2a and 2c receptors; it is well absorbed, with a mean half-life of 30 h, and is metabolized by the cyp 1a2, cyp2 D6 and flavin mono-oxygenase system. The CYP2D6 is a minimally involved system, thus there should be minimal concern for drug interactions with potent inhibitors of this system. Olanzapine has no active metabolite[42].

The most frequent untoward events seen with olanzapine are hypotension, constipation, weight gain, somnolence, agitation and dizziness[42]. It does have anticholinergic side effects, and can cause significant weight gain, which may be an advantage for those elderly patients who have suffered significant weight loss. The optimally recommended dose range is 2.5–15 mg/day.

An ad hoc study reviewing the olanzapine data in those over the age of 65 with psychotic disorders found no significant difference between the elderly and younger patients. Dose comparisons were similar for patients younger and older than 65[43,44]. A study using olanzapine in patients with dementia of the Alzheimer's type showed no difference in efficacy from the placebo group at doses in the range 1–8 mg/day. This same study found no difference in liver function test, EPS, leukopenia or orthostasis when compared to placebo[45]. Although olanzapine appears to have anticholinergic side effects, these were not significantly different from those seen in comparison to a placebo group[43]. Olanzapine was found to be well tolerated and safe in the elderly. Doses used are similar to those for younger patients; initial doses should be 2.5–5.0 mg/day. Olanzapine has the added advantage of once daily dosing.

Quetiapine

Another novel antipsychotic recently FDA-approved for use in the USA is quetiapine. Quetiapine is a dibenzothiazepine derivative. It exhibits higher affinity for 5-HT_2 receptors than for dopamine D2 receptors and is reported to have greater affinity for the mesolimbic than the nigrostriatal sites, thus accounting for its effect on positive symptoms with minimal EPS[46,47]. Quetiapine is reported to treat both the positive and negative symptoms of schizophrenia[46,47]. The incidence of EPS has been found to be minimally no different than placebo.

In a study of elderly patients with psychotic disorders, the average dose of quetiapine was 100 mg/day. In that same study the most frequent side effects found were somnolence (32%), dizziness (14%), postural hypotension (13%) and agitation (11%). However, from a cardiovascular perspective, the patients did exhibit a slight increase in their heart rate but there were no changes in the QRS complex. No hematological changes were noted, except for a non-significant slight increase in t4 not associated with substantial changes in the mean thyroid-stimulating hormone levels. Quetiapine was rarely associated with weight gain. These authors recommended starting at a dose of 25 mg/day and titrating to a target dose of 100 mg/day in divided doses. Most patients will be treated with doses in the range 100–300 mg/day, with an occasional patient requiring higher doses[46,48].

Ziprasidone

A new atypical antipsychotic currently awaiting FDA approval in the USA is ziprasidone. Ziprasidone is reported to have affinity for the dopamine D2 and D3 receptors and the agonist of 5-HT_2. It has negligible affinity for the other receptors of concern in the elderly, including α-2 and β-muscarinic; it moderately inhibits the reuptake of serotonin and norepinephrine but weakly effects the reuptake of dopamine[49,50]. This drug is potentially effective for both positive and negative symptoms and depression, with a low likelihood of causing EPS[49].

The following studies have looked at the use of ziprasidone in younger patients, the oldest being 64. Patients with acute exacerbation of schizophrenia and schizoaffective disorder had a better response than placebo on both 80 mg/day and 160 mg/day[50]. Often patients with these disorders are suffering from depression; in this same study 160 mg of ziprasidone was found to be effective to treat depression[50]. Other studies have reported that a dose of 120 mg/day was more effective than 40 mg/day. The side

effects reported included dyspepsia, transient somnolence, constipation, nausea and abdominal pain[49]. Ziprasidone was associated with a lower incidence of EPS and postural hypotension, with no weight gain or laboratory abnormalities[49].

Risk Factors for Dyskinesia in the Elderly

Thomas R. E. Barnes
Imperial College School of Medicine, London, UK

TARDIVE DYSKINESIA

Clinical Features

In the mid-1950s, within a few years of the introduction of antipsychotic drugs, clinicians drew attention to "neurotoxic reactions" to this treatment. In addition to parkinsonian features, involuntary orofacial movements were noted[1,2]. Sigwald *et al.*[3] are usually credited with the first detailed description of "facio-bucco-linguomasticatory dyskinesia" associated with these drugs. In the early 1960s, Faurbye *et al.*[4] coined the term "tardive dyskinesia" for this condition.

Abnormal involuntary orofacial movements remain the most familiar and prevalent features of tardive dyskinesia. The movements are irregular, stereotyped and choreic in nature, and tend to involve the tongue, lips, jaw and face, including the peri-orbital areas. The movements observed include protrusion or twisting of the tongue, lip smacking, cheek puffing, pursing and sucking actions of the lips, and chewing and lateral jaw motions. The particular combinations of movement seen vary considerably between patients but tend to be relatively consistent for each individual.

In addition to these orofacial phenomena, most descriptions of tardive dyskinesia include a variety of trunk and limb movements. These are typically choreiform or choreoathetoid in type, although athetosis of extremities, and axial and limb dystonia, are often listed as part of the syndrome, as are abnormalities of gait and trunk posture, such as lordosis, rocking and swaying, shoulder shrugging and rotary movements of the pelvis. Grunting and respiratory arrhythmias are also seen.

The notion that orofacial and limb and trunk dyskinesia represent distinct pathophysiological entities with different risk factors and clinical correlates[5] seems to hold true in older patients[6]. For example, Paulsen *et al.*[7] studied middle-aged and elderly outpatients starting antipsychotic drug treatment and obtained systematic follow-up data over 2 years. They found that the cumulative incidences and the significant predictors identified differed for the two subsyndromes.

Prevalence, Incidence and Natural History

While tardive dyskinesia is a common problem in those individuals receiving antipsychotic drug treatment long-term, the majority will not exhibit the condition. The reported prevalence figures vary widely, from 0.5% to 56%[8,9], reflecting variables such as the age of the sample studied (see below) and the sensitivity of the rating instrument used. Overall, the literature suggests that only 20% or so of drug treated patients will develop the problem, and of these, the dyskinesia is likely to be serious in less than 10%. Gardos *et al.*[10] concluded that the severe tardive dyskinesia is very uncommon, occurring in approximately 1/100–1/1000 patients with the condition. Nevertheless, in elderly psychiatric inpatients, prevalence figures of around 50% or greater are not uncommonly reported[6].

The prospective study of Kane *et al.*[11,12] suggested that new cases of tardive dyskinesia can occur at a rate of 3–4% a year in the first few years after starting antipsychotic medication. However, there is only limited information available to guide the clinician as to who might be most at risk. Tardive dyskinesia was originally considered irreversible, although follow-up studies[13,14] have revealed that it is not a progressive disorder, but rather tends to fluctuate in severity over time. Spontaneous remissions are relatively common, particularly in younger patients. Such a view of the natural history of tardive dyskinesia in patients on chronic drug treatment was reinforced by the results of two 10 year follow-up studies by Yagi and Itoh[15] and Casey and Gardos[16].

To some degree, these findings might be seen as relatively reassuring, allaying earlier fears that tardive dyskinesia was a major iatrogenic condition that would constrain the use of long-term antipsychotic drug therapy. However, while the condition itself is rarely disabling, it can be socially stigmatizing. Further, severe tardive dyskinesia can be a troublesome problem, particularly in the elderly. Orofacial dyskinesia can interfere with eating and swallowing, render speech unintelligible, and cause breathing difficulties, sometimes leading to dysphagia or choking[17–19]. Trunk and limb dyskinesia may be associated with disturbances of gait that can lead to falls and injury[20].

RISK FACTORS

Advancing Age

In numerous studies, advancing age has been clearly shown to be a major vulnerability factor for tardive dyskinesia. It is associated not only with an increased occurrence of tardive dyskinesia but also with greater severity and a reduced likelihood of spontaneous remission[9,21]. Studies involving geriatric patients have consistently found a higher incidence of tardive dyskinesia with conventional antipsychotics, even at low doses[22,23]. Examining pooled epidemiological data has revealed a strong linear correlation between age and both the prevalence and severity of tardive dyskinesia[24]. However, duration of exposure to antipsychotic drugs is a confounding variable, as older patients are likely to have received

drug treatment for longer; i.e. age-group and length of time on drug treatment would be expected to be linked. Nevertheless, clinical studies have consistently shown an effect of age independent of that attributed to length of drug treatment[9,13]. Further, it would seem that the older patients are when they first receive antipsychotic medication, the more likely they are to develop the condition early in treatment[25]. This was dramatically demonstrated in a prospective study of tardive dyskinesia in patients 55 years or older who were just beginning antipsychotic drug treatment[26]. These investigators initially presented preliminary data on 160 patients[27] and subsequently reported on the complete study group of 261 patients[26]. Patients were assessed at 3 month intervals. After approximately 1, 2 and 3 years of cumulative exposure to antipsychotic medication, the incidence figures for tardive dyskinesia in the larger sample were 25%, 34% and 53%, respectively. These investigators concluded that the rate of tardive dyskinesia for patients over 50 years of age starting antipsychotic drug treatment was three to five times that reported in younger adults.

Much of the variation in incidence and prevalence figures reported in the published literature is likely to be due to age differences in the sample studied[9]. The results of a 3 year follow-up study of tardive dyskinesia by Barnes *et al.*[13] suggested that patients receiving antipsychotic drugs may be most likely to develop the condition in their sixth decade. Jeste *et al.*[28] calculated that in the sample of chronically ill, schizophrenic inpatients they studied, the probability of having tardive dyskinesia was greater than 0.4 in those patients over 65 years old. In their review of the literature, Smith and Baldessarini[24] pointed out that the rise in prevalence with age may partly reflect the relative persistence of tardive dyskinesia in older patients. They concluded that tardive dyskinesia in those less than 60 years of age was over three times more likely to remit spontaneously. However, as the relevant studies included patients either withdrawn from antipsychotic medication or on extended "drug holidays", this conclusion partly reflects the reversibility of the condition after drugs are discontinued. Younger patients appear to possess a greater recovery potential when medication is withdrawn, but whether they show a higher spontaneous remission rate than older patients when maintained on chronic antipsychotic drug therapy remains unconfirmed. Work with an animal model of tardive dyskinesia suggests that spontaneously remitting dyskinesia emerging early in drug treatment can become irreversible with prolonged drug therapy[29].

Antipsychotic Medication

While it seems plausible that the relationship between exposure to antipsychotic treatment and vulnerability to tardive dyskinesia varies with age, such a relationship has not been systematically tested. In the minority of studies where a relationship between specific drug variables and tardive dyskinesia has been found, it has tended to be within the first few years of treatment[9,11], particularly in studies of elderly populations[30–32]. For example, Jeste *et al.*[21] studied 266 patients over 45 years of age receiving conventional antipsychotic medication. At baseline, the median duration of total lifetime antipsychotic exposure was only 21 days. Over the first 3 years, the cumulative incidence of tardive dyskinesia was 26%, 52% and 60%, respectively. The main risk factors for the appearance of tardive dyskinesia included baseline duration of antipsychotic treatment of over 90 days, and the cumulative amount of antipsychotic medication prescribed, particularly "high-potency" drugs. This group of investigators[33] also examined risk factors specifically for severe tardive dyskinesia. In a prospective study of 378 older neuropsychiatric patients over 3 years, the incidence of severe tardive dyskinesia was 2.5% in the first year, 12% in the second and 23% in the third. As in the earlier study, higher daily doses of antipsychotic medication at baseline and greater cumulative amount of prescribed antipsychotic emerged as risk factors. In the study by Woerner *et al.*[26] mentioned above, higher mean daily dose of antipsychotic and cumulative dosage were also found to be associated with a greater risk of developing tardive dyskinesia.

The mechanisms whereby advancing age exerts an influence on susceptibility to tardive dyskinesia remain speculative. It is possible that neuropathological and/or neurochemical changes occurring with age may be associated with an increasing prevalence of tardive dyskinesia. Neuronal damage or degeneration, receptor changes and the reduced efficiency of adaptive homeostatic processes may well underlie the vulnerability of certain drug-induced neurological side effects in older patients. The development of supersensitive post-synaptic dopamine receptors in the basal ganglia remains the accepted explanation of the pathophysiology of tardive dyskinesia. However, such supersensitivity would seem to be an inevitable consequence of prolonged antipsychotic drug treatment, and is therefore insufficent to explain why only a proportion of patients on long-term medication develop dyskinesia[34]. An interaction between drug-induced receptor changes in the striatum, and age-related degenerative effects in the nigrostriatal system may be necessary for the appearance of tardive dyskinesia.

Pharmacokinetic mechanisms could also be relevant. Age-related changes in the absorption, metabolism and excretion of drugs may lead to higher plasma drug levels and delayed clearance. Plasma levels of antipsychotic drugs have been found to be raised in the elderly, compared with younger patients[35,36].

Atypical Antipsychotics

The newer, atypical antipsychotics are characterized by a lower liability for extrapyramidal side effects and, for some of these agents, evidence is emerging for a lower risk of tardive dyskinesia[37]. However, thus far, there have only been a few studies addressing the safety and tolerability of these drugs, at appropriate dosage, in the elderly. For reasons addressed briefly above, the findings of clinical trials in young adults may not be reliably extrapolated to the elderly, for whom dosage requirements tend to be lower[38,39]. Preliminary clinical data suggest that newer agents such as risperidone and olanzapine may be relatively well tolerated in older people[40] and there have been similar claims for low-dose clozapine[41], but well-designed, controlled studies in the elderly are required[42,43].

In respect of tardive dyskinesia risk in the elderly, risperidone has been the atypical antipsychotic most commonly studied. Over a period of 9 months, Jeste *et al.*[44] found a significantly lower incidence of tardive dyskinesia in older patients treated with risperidone as opposed to haloperidol. The patients were middle-aged or elderly (mean age 66 years) and had not received previous treatment with antipsychotics. "Clinically comparable" groups receiving treatment with either risperidone or haloperidol were compared. The median dose for both drugs was 1 mg/day. The haloperidol-treated patients proved to be significantly more likely to develop tardive dyskinesia. A further study by the same group of investigators[45] addressed the risk of persistent tardive dyskinesia with risperidone in elderly patients with dementia. In an open study, a sample of 330 patients (mean age 82.5 years) received risperidone in flexible dosage (mean modal dose 0.96 mg/day) over a year. Amongst the 255 patients with no evidence of tardive dyskinesia at baseline, the 1 year cumulative incidence of the condition was 2.6%, and patients who had exhibited dyskinesia at baseline experienced significant improvement. The investigators concluded that such

an incidence was much lower than would be expected with conventional antipsychotic treatment in such patients. A similar conclusion was reached by Davidson *et al.*[46], who conducted an open study of risperidone in a sample of 180 elderly, chronically-ill, psychotic patients (median age 72 years) over 1 year; 97 of those in the sample received risperidone for the full 12 months. At the endpoint, the mean dose of risperidone was 3.7 mg/day. Only six cases of persistent tardive dyskinesia emerged during the study period, representing an incidence of 4.3%.

Preliminary evidence also raises expectations of a relatively lower risk of tardive dyskinesia in the elderly with olanzapine[18,47] and possibly quetiapine[18].

Gender

A relatively consistent finding has been that women show a greater prevalence of severe dyskinesia, although there is evidence to suggest that this is limited to the geriatric age range, that is, over 60 years of age[9,48,49] and the more severe cases[50,51]. The ability to detect a significant effect for gender is probably related to the size of the study sample and the base rate of tardive dyskinesia in the population being studied. Nevertheless, Smith and Dunn[52] identified 13 studies reporting statistically significant differences supporting female vulnerability, with the average unweighted female:male prevalence ratio in the patient samples being 1.69.

For example, Ramsay and Millard[53], in a sample of 426 elderly subjects, predominantly geriatric or psychogeriatric inpatients, found dyskinetic movements in 12.5% of women but only 7.6% of men. In a sample of patients over 65 years with senile dementia of the Alzheimer type, O'Keane and Dinan[54] found that significantly more females (89%) had evidence of orofacial dyskinesia compared with the males (60%). However, the prospective study of tardive dyskinesia in the elderly, conducted by Woerner *et al.*[26], failed to find a significant relationship between sex and incidence of the condition. Indeed, the incidence was slightly higher for males, although they were significantly younger than the females.

Richardson *et al.*[55] reported that females showed an increase in prevalence of tardive dyskinesia in all age groups up to and beyond 75 years, while males only demonstrated an increase up to 75 years, with a decline subsequently. The differences in prevalence between the sexes was minimal up to 64 years using mild severity to define a case, but female prevalence was substantially higher when a criterion of moderate to high severity was applied. These findings support the view that the magnitude of sex differences in tardive dyskinesia is dependent on the severity of the criteria used to define the disorder, as well as the age of the sample[50,51].

As a vulnerability factor, gender is far weaker than age, with which there seems to be an interaction. There is no clear explanation for the female preponderance, although it has been suggested that neuroendocrine factors may be relevant. Oestrogen and prolactin may influence striatal dopamine function[56], and the reduced ovarian function in post-menopausal women, with low oestradiol levels, may increase vulnerability to tardive dyskinesia[57,58]. However, rather than a direct reflection of gender, it has been variously speculated that female sex is a proxy variable for longer duration of hospitalization, higher drug dose and longer duration of treatment.

Organicity

Reviews of the risk factors for tardive dyskinesia[59–61] suggest that in patients with schizophrenia, evidence of "organicity" is a marker of vulnerability to tardive dyskinesia. Putative, indirect indices of organicity, such as soft neurological signs and cognitive impairment, computed tomography (CT) evidence of structural brain pathology and the presence of negative symptoms, have all been found more commonly in patients with tardive dyskinesia than those without. Thus, ageing may be a predisposing factor for tardive dyskinesia only insofar as it increases the likelihood of organic brain dysfunction.

Hunter *et al.*[62] and Crane and Paulson[63] surveyed mixed psychiatric inpatient populations and found tardive dyskinesia to be more prevalent in patients with organic mental syndromes than in those with schizophrenia. Yassa *et al.*[64] conducted a similar study, assessing over 300 psychiatric patients treated with antipsychotic drugs. They also found that patients with organic mental syndromes, including those diagnosed as epilepsy with psychosis and mental retardation with psychosis or alcoholism, showed a significantly higher prevalence of tardive dyskinesia compared to those with schizophrenia. A number of organic mental syndromes and neuromedical conditions, such as multi-infarct dementia, strokes and cerebral tumour, are more common in older individuals, and this may partly explain why the prevalence of tardive dyskinesia is greater in elderly samples[65,66]. However, any such hypothesis should take account of the influence of the range of other psychiatric diagnosis in such samples. For example, Yassa *et al.*[64] found that patients with a primary bipolar affective disorder had the same prevalence of tardive dyskinesia as those with organic mental syndromes. In their prospective study in the elderly, Woerner *et al.*[26] reported that the risk of tardive dyskinesia in individuals with multi-infarct dementia was similar to that for people with mood disorder, while patients with Alzheimer's disease and other organic mental syndromes showed a lower rate.

Psychiatric Diagnosis

Affective Disorder

Recent work has highlighted affective disturbance as a possible relevant variable. Both a positive family history of affective disorder and the presence of depressive features in patients with schizophrenia have been mooted as markers of an increased likelihood of developing both parkinsonian side effects and tardive dyskinesia, but the evidence is tentative at present. However, there is accumulating evidence that patients with primary affective disorder may be at particular risk of tardive dyskinesia if administered antipsychotic drugs long-term. A report by Davis *et al.*[67] noted the relatively high prevalence of tardive dyskinesia among such patients and this has been confirmed by later studies[68–70].

The preliminary data from the prospective study of tardive dyskinesia by Kane *et al.*[19] provides additional support for a diagnosis of affective disorder as a vulnerability factor. A life-table analysis based on the length of drug administration, and comparing the cumulative incidence of tardive dyskinesia in patients with affective or schizoaffective disorder with that of inpatients with a diagnosis of schizophrenia, revealed that the former have a significantly greater incidence after 6 years of exposure to antipsychotic drugs. The incidence figures were 26% for the affective and schizoaffective patients compared with 18% for those with schizophrenia. Further evidence was provided by Mukherjee *et al.*[71], who found persistent tardive dyskinesia in 35% of a sample of bipolar patients who had received maintenance antipsychotic drugs, while no patients without such a drug history had persistent dyskinesia.

Schizophrenia

The schizophrenic illness itself may be a risk factor[59,61]. Long before the advent of antipsychotic drugs, a variety of motor disorders were described in psychiatric patients, particularly those with catatonic schizophrenia[72–74] and other types of schizophrenia[75–77]. These movements would seem to be principally disturbances of voluntary motor activity and may be classified as stereotypes and mannerisms, preservative movements, tics, grimaces and general clumsiness, awkwardness and lack of coordination. However, Kraepelin[78], and then later Farran-Ridge[75], observed spasmodic movements, mainly involving the orofacial muscles, which they considered choreiform in nature.

Nevertheless, Marsden *et al.*[79] concluded that true chorea and athetosis were scarce in chronic psychiatric patients before drug treatment, and that much of the motor disorder seen was attributable to organic neurological disorder, such as encephalitis and syphilis. Further, the terminology used is confused, reflecting various conceptual notions of the aetiology of the motor phenomena observed[80,81]. Kleist[73] and Farran-Ridge[75] commented that the similarity between the manifestations of dementia praecox and epidemic encephalitis was such that difficulties in differential diagnosis could arise. However, there is no doubt that some of the movements described would be scored on current rating scales for tardive dyskinesia if seen now in patients receiving antipsychotic drugs.

There would seem to be three possible interpretations of these observations[59]. First, the type of motor disturbance historically described is not specifically associated with schizophrenia, but rather the product of organic brain disease. The two conditions also occur together when the brain disease is also responsible for symptomatic schizophrenia, as, for example, when schizophrenia appears in patients with encephalitis, Wilson's disease or Huntington's disease, among other conditions[82]. Second, the association of motor disturbance and schizophrenia may be more specific, in that an underlying neuropathological process is capable of producing both psychological and motor impairments. Third, as Kraepelin and Bleuler tended to suggest, the movements may be secondary to the schizophrenic disturbance of will, thought and emotion. However, the distinctions between the three explanations cannot be too sharply drawn, and more than one may be relevant.

In a relevant contemporary study, Owens *et al.*[83] compared chronic schizophrenia inpatients with and without a history of antipsychotic drug treatment, and found a similar prevalence of abnormal involuntary movements in the two groups. This finding confirmed the occurrence of spontaneous movement disorder in schizophrenia. However, the contribution of drug therapy was acknowledged, in that when the age difference between the two patient samples was taken into account in further analysis of the data, there was a significant linear relationship between the prevalence of abnormal involuntary movements and exposure to antipsychotic drugs[84]. Grouping movements into clinically recognizable syndromes revealed a particular susceptibility to orofacial dyskinesia in the drug-treated patients. Nevertheless, the schizophrenic illness, at least in some forms, may be seen as a psychomotor disorder with an inherent, increased risk of dyskinesia. Antipsychotic drug treatment may interact with the disease process and age-related cerebral deterioration to hasten or provoke the appearance of such movement disorder[59,85].

Dementia

Accepting that organicity is a risk factor for tardive dyskinesia, it might be expected that the neurodegenerative changes of Alzheimer's disease would be associated with a relatively high risk of spontaneous dyskinesia and also a greater risk of tardive dyskinesia when antipsychotic drugs are administered. Molsa *et al.*[86] assessed abnormal involuntary movements in 177 patients with Alzheimer's disease, with a mean age of 75 years. In the 143 patients who had never received antipsychotic drugs, the prevalence of dyskinesia was 17%, while for the 34 patients treated with antipsychotic drugs the figure was 53%. As part of a larger study, Ramsay and Milard[53] looked at 40 patients on long-stay psychogeriatric wards. Of the 13 (32.5%) patients with dyskinesia, 12 had a history of treatment with antipsychotic drugs. These findings suggest a vulnerability to tardive dyskinesia in dementia patients receiving antipsychotic drugs.

O'Keane and Dinan[54] assessed 78 patients with an age range of 65–91 years, all of whom fulfilled DSM-III criteria for senile dementia of the Alzheimer type. The scales used included the Mini-Mental State (MMS)[87] and Abnormal Involuntary Movements Scale (AIMS)[88]. They reported that 62 patients (69%) had evidence of orofacial dyskinesia, a figure the authors noted to be over 10 times that reported in healthy elderly adults, and also considerably higher than the prevalence found in populations of patients with chronic schizophrenia. Orofacial dyskinesia was by far the most common abnormal movement rated. The mean doses of antipsychotic drug for those with and without abnormal movements were modest, and although the former group was receiving a higher mean dosage, the differences between the two groups was not statistically significant.

Molsa *et al.*[86] found that the severity of orofacial dyskinesia in their sample of patients with Alzheimer's disease increased with the degree of cognitive deficit. Bakchine *et al.*[89] studied a group of 91 patients with dementia of the Alzheimer type and examined the relationships between primitive reflexes, extrapyramidal symptoms and severity of cognitive impairment. They failed to find any significant relationship between ''buccolinguofacial dyskinesias'' and a low score on intellectual functioning, but their methodology was criticized by O'Keane and Dinan[54], who pointed out that they only rated abnormal movement as either present or absent, rather than qualifying the movements using a standardized scale. In their own study O'Keane and Dinan found that there were no significant differences in terms of age or length of illness between those patients with and without abnormal movements, and both groups showed evidence of severe intellectual impairment. However, those patients with abnormal movements had a significantly greater degree of cognitive impairment, as judged on mean MMS scores. On the basis of this finding, O'Keane and Dinan suggested that orofacial dyskinesia might prove to be a useful indicator of the severity of intellectual decline in patients with Alzheimer's disease.

Acute Extrapyramidal Side Effects: Parkinsonism and Akathisia

Susceptibility to acute drug-induced extrapyramidal side effects as a predictor of tardive dyskinesia was first suggested by Crane in 1972[90]. He considered that tardive dyskinesia was more likely to emerge in patients who had developed parkinsonism as an acute side effect of antipsychotic drug treatment than in those who had not.

Based on clinical observation, Chouinard *et al.*[91] suggested that patients with tremor or akathisia, which they described as ''hyperkinetic'' symptoms of parkinsonism, were more likely to manifest tardive dyskinesia than patients with ''hypokinetic'' symptoms, such as bradykinesia and rigidity. De Veaugh-Geiss *et al.*[92] elaborated on this idea, suggesting that in some cases akathisia represented a stage in a progression from parkinsonism to the development of orofacial and trunk and limb dyskinesia. Consistent with this notion, Barnes and Braude[93] reported two

cases where the appearance of akathisia at the beginning of drug therapy, which then persisted despite the reduction of drug dosage to maintenance levels, seemed to herald the early onset of tardive dyskinesia.

Thus, a variety of study findings and case reports suggest that patients presenting with symptoms of parkinsonism and acute akathisia are more likely to manifest tardive dyskinesia. More convincing evidence is available from a prospective study of risk factors for tardive dyskinesia carried out by Kane *et al.*[11]. Analysis of the data from the first 5 years of their follow-up study suggested that a history of early, clinically significant parkinsonism indicated susceptibility to the subsequent development of tardive dyskinesia, particularly for those patients developing tardive dyskinesia within the first 2 years of exposure to antipsychotic drugs. The patients in this study were relatively young, the mean age of the 800 patients originally recruited being 27 years. Further supportive evidence was provided by the prospective studies of elderly patients conducted by these investigators[26,27]. Individuals exhibiting signs of acute extrapyramidal side effects, i.e. parkinsonism and akathisia, early in treatment with antipsychotic drugs showed a greater vulnerability to tardive dyskinesia.

If susceptibility to akathisia is associated with susceptibility to tardive dyskinesia, it might be expected that the two conditions would commonly coexist in patients chronically treated with antipsychotics. Several studies have found this to be the case[13,94]. For example, Barnes and Braude[95] reported that 39% of schizophrenic outpatients with chronic akathisia also had orofacial dyskinesia. Further, out of 52 cases of chronic akathisia, Burke *et al.*[96] found that all but one had either orofacial dyskinesia (63%), tardive dystonia (8%) or both (27%). Dufresne and Wagner[97] also reported an association between the two conditions. In 33 chronic schizophrenic patients, these investigators found that the mean AIMS score (see earlier) was significantly higher in those patients with akathisia compared with those without the condition.

SPONTANEOUS DYSKINESIA

A condition described as spontaneous or idiopathic orofacial dyskinesia has been noted in psychiatric inpatients, predominantly elderly, who have never received antipsychotic drugs[8,98–100]. The prevalence figures in the literature vary from 0% to around 37%, but it is not always clear whether the hyperkinetic movements disorders reported represent senile chorea, spontaneous orofacial dyskinesia or senile dyskinesia[101,102]. These spontaneous orofacial movements show an increase in incidence with age. In a sample of 661 patients, Klawans and Barr[103] found a prevalence of 0.8% between the ages of 50 and 59, 6% between 60 and 69 years, and nearly 8% in patients between 70 to 79 years.

Crane[104] has stated that "chronicity of disease and/or institutionalization with attendant emotional and physical deprivation" may be responsible for these abnormal movements, being a common factor in both drug-treated and non-drug-treated psychiatric inpatients. Nevertheless, Altrocchi[105] reported two outpatients presenting with spontaneous orofacial dyskinesia, and this condition has also been observed as a relatively rare phenomenon in non-psychiatric, drug-free residents in old-age homes[48,49]. It has been estimated that this condition is present in some 2% of the geriatric home population[106,107], although Varga *et al.*[108] surveyed a population of elderly people never exposed to antipsychotic drugs and discovered that 10% had clear evidence of oral dyskinesia. In a similar sample, Bourgeois *et al.*[109,110] found that 18% exhibited "buccolinguofacial dyskinesia". These cases of spontaneous orofacial dyskinesia are generally considered to be indistinguishable from orofacial tardive dyskinesia, although subtle differences in the distribution of movements have been detected between elderly psychiatric patients who were receiving antipsychotic drugs and normal elderly individuals who were drug-naïve[111].

Blowers *et al.*[112] surveyed 500 elderly residents in local authority homes using the AIMS. Out of the 378 individuals who had never received antipsychotic drugs, 50 (15%) were diagnosed as having "tardive dyskinesia" as they scored 3 or more on the AIMS global assessment scale. However, the AIMS may have limitations as a diagnostic scale[113,114].

These data generally suggest that elderly individuals are at a greater risk of spontaneous dyskinesias and abnormal involuntary movements related to various neurological and medical conditions independent of antipsychotic drugs. Nevertheless, surveys of normal elderly subjects suggest that spontaneous dyskinesias are relatively uncommon in the absence of brain disease or dysfunction.

SUMMARY

Elderly individuals would seem to be particularly vulnerable to the development of tardive dyskinesia when administered antipsychotic drugs, with females and those patients with dementia, other neurodegenerative conditions and organic brain syndromes being perhaps especially at risk. A diagnosis of affective disorder and the development of acute extrapyramidal side effects, such as parkinsonism and akathisia, when starting antipsychotic medication should also serve as warnings of a higher risk for tardive dyskinesia observed in elderly populations. Preliminary data suggest that use of the newer atypical antipsychotics, rather than conventional antipsychotics, in the elderly may substantially reduce the proportion developing tardive dyskinesia. A proportion of the orofacial dyskinesia observed in elderly populations, between 5% and 15% according to the majority of studies, will be spontaneous dyskinesia of the elderly. This is a condition virtually indistinguishable from tardive dyskinesia.

Nosology and Classification of Neurotic Disorders

D. Bienenfeld

Wright State University School of Medicine, Dayton, OH, USA

The grouping of a variety of psychopathologic entities under the heading of "neurotic disorders" represents the current attempt to solve a nosological tangle dating back further than the time of Sigmund Freud. The contemporary categorization is controversial and less than satisfying to many. A brief look at its historical roots offers some explanation of the sense behind the current ICD-10 and DSM-IV structures.

HISTORY OF THE CLASSIFICATION OF THE NEUROSES

It was Hippolyte-Marie Bernheim who introduced the term "psychoneurosis" for hysteria and allied conditions. Freud, who studied with Bernheim, differentiated the "actual neuroses" (including neurasthenia, anxiety neurosis and hypochondria) from the psychoneuroses. The latter category included not only the "transference neuroses", such as hysteria and obsessive neurosis, but also the psychoses (paraphrenia, schizophrenia, paranoia and manic depression), perversions and neurotic character. Both types of neurosis were related to sexual disturbance; the actual neuroses were direct somatic consequences of a noxious physical influence resulting from misdirected sexual energy; the psychoneuroses were caused by unconscious conflict between instinctual and counter-instinctual forces[1]. Although Freud's thinking on the precise nature of the mental etiology of the psychoneuroses changed over the years from about 1894 to 1906, he remained consistent in his stance that the psychoneuroses were defined by their etiology rather than by their phenomenology[2]. Eventually, the psychoses were classified independently, consistent with the views of Kraepelin.

In 1952, the American Psychiatric Association published the first *Diagnostic and Statistical Manual of Mental Disorders* (DSM-I). It identified the subtypes of psychoneurotic disorders as anxiety, dissociative, conversion, phobic, obsessive-compulsive, and depressive reactions[3]. By the mid-1960s, the major diagnostic schemata, ICD-8 and DSM-II, codified the selection of the descriptive framework for identifying the neuroses. Anxiety was seen as the chief characteristic, whether felt and expressed directly or diverted unconsciously into other symptoms. The neuroses were also grouped by severity; they were more specifically symptomatic than the personality disorders, but entailed no gross distortion or impairment of reality testing, as in the psychoses. Categories included in the 300-code section were anxiety, hysterical, phobic, obsessive-compulsive, depressive, neurasthenic, depersonalization and hypochondriacal neuroses. Transient situational disturbances constituted their own category (code 307)[4].

The descriptive focus was emphasized in ICD-9 with the substitution of the term "neurotic disorders" for "neuroses", although the categorization was not significantly modified[5]. In 1980, the American Psychiatric Association published the DSM-III[6], which took a substantial leap towards atheoretical descriptive diagnosis by adopting empirically validated criteria based on research diagnostic criteria. One of the most controversial changes was the elimination of the entire class of neuroses. The neurotic disorders were included in the affective, anxiety, somatoform, dissociative and psychosexual disorders[7]. The grouping by severity was abandoned in favor of clusters based on similarity of features. The diagnostic entities retained numerical codes compatible with ICD-9 and ICD-9-CM.

The other revolutionary change introduced with DSM-III was the use of a multiaxial system for diagnosis. Under this scheme, personality disorders, which often predispose individuals to the development of specific neurotic (and other) syndromes, were relegated to a separate and parallel Axis II. The 1987 revision, DSM-III-R, changed some names and criteria but retained the same hierarchy of the neurotic disorders and the same multiaxial formula[8]. DSM-IV, published in 1994, was a more substantive revision overall than DSM-III-R, with only a few changes relevant to the neurotic disorders. The diagnosis of Acute Stress Disorder was added for compatibility with ICD-10. Dissociative Identity Disorder was added to Axis I to replace Multiple Personality Disorder, which was removed from Axis II. Simple Phobia was renamed Specific Phobia for compatibility with ICD-10[9].

Neurotic Disorders in ICD-10 and DSM-IV

The creators of ICD-10 were faced with a formidable challenge, as this version, unlike its nine predecessors, was to be designed as the last of the series to be scheduled for regular revisions[10]. It therefore had to contain a format that would allow for flexibility in minor revisions while establishing a more permanent structure than versions 1–9. While following the lead of the phenomenological school in separating out a major category for mood disorders that includes both psychotic and neurotic levels of severity, it retains the major classification of neurotic disorders, including somatoform disorders and stress-related disorders[11]. This grouping solves the objection that the term "neurosis" groups together entities which could be better classified, e.g. by placing neurotic severities of depression together with other mood

Table 97.1 Relative positions of neurotic disorders in the diagnostic schemata

ICD-10	DSM-IV
F0 Organic mental disorders	Disorders usually first evident in infancy, childhood or adolescence
F1 Mental and behavioral disorders due to psychoactive substance uses	Delirium; dementia and amnestic and other cognitive disorders
F2 Schizophrenia, schizotypal states and delusional disorders	Mental disorders due to a general medical condition not elsewhere classified
F3 Mood disorders	Substance-related disorders
F4 NEUROTIC, STRESS-RELATED AND SOMATOFORM DISORDERS	Schizophrenia and other psychotic disorders
F5 Behavioral syndromes and mental disorders associated with physiological dysfunction and hormonal changes	Mood disorders
	ANXIETY DISORDERS
F6 Abnormalities of adult personality and behavior	SOMATOFORM DISORDERS
F7 Mental retardation	DISSOCIATIVE DISORDERS
F8 Developmental disorders	Factitious disorders
F9 Behavioral and emotional disorders with onset usually occurring in childhood or adolescence	Sexual and gender identity disorders
	Eating disorders
	Sleep disorders
	Impulse-control disorders not elsewhere classified

disorders, rather than with anxiety disorders. It does, however, retain the historical commonality that traces to Freud's original stress on the etiologic similarity of the psychoneuroses, acknowledging the current state of scientific knowledge that is, at best, ambiguous concerning the etiology of these disorders[12,13].

Table 97.1 compares the relative positions of the neurotic disorders in ICD-10 and Axis I of DSM-IV. The alphanumeric organization of the International Classification requires the constraint of all mental disorders to 10 major categories. DSM-IV, under no such limitation, separates out anxiety, somatoform and dissociative disorders but keeps them within the same gradient of severity between mood disorders and sexual disorders. Adjustment disorders are removed to a position implying less severity, as well as an implied direction that higher-ranking diagnoses are to be made or eliminated first. Personality disorders, of course, are assigned to Axis II.

Under the category of the neurotic disorders, the international and American systems differ in their organization, as outlined in Table 97.2. DSM-IV groups the phobic disorders, obsessive-compulsive disorder, post-traumatic stress disorder and generalized anxiety disorder together as anxiety disorders. ICD-10 separates phobic disorders, anxiety disorders, and obsessive-compulsive disorders. Post-traumatic stress disorders are classified with adjustment disorders. Both schemes separate dissociative and somatoform disorders. ICD-10 groups conversion disorder with dissociative states, consistent with the historical, etiologically-based classification of the hysterias. DSM-IV combines it with the somatoform disorders, based on their phenomenological similarities. ICD-10 retains the diagnosis of neurasthenia; while DSM-III-R refers the clinician to dysthymia, categorized unequivocally as a mood disorder, DSM-IV eliminates the term entirely[8,9,11].

DIAGNOSTIC FEATURES OF NEUROTIC DISORDERS

While each of the major categories of neurotic disorders is described in the chapters that follow, the clinical features of the seven ICD-10 groupings are presented here for overview and comparison[11].

Phobic disorders are a set of disorders in which anxiety is invoked only, or predominantly, by well-defined situations that are not in themselves dangerous. By definition, the object of the fear is external to the individual, so that fears of bodily processes are more appropriately relegated to the category of somatoform disorders. The feared objects are characteristically avoided, and anticipatory anxiety is common.

Other anxiety disorders are those in which anxiety is the major symptom but which are not restricted to specific situations. They include panic disorder, generalized anxiety disorder, and mixed anxiety and depressive disorder. The latter is reserved for cases where symptoms of both are present, neither is predominant, and the depression is not severe enough to be classified under mild depressive disorder.

Obsessive-compulsive disorder is characterized by recurrent obsessional thoughts or compulsive acts, or both. These thoughts and acts are subjectively distressing. Subjective anxiety is usually present and depressive features are common.

Reactions to severe stress and adjustment disorders represent a unique category, in that the component disorders are identified on the grounds of both symptomatology and causation. In these disorders, anxiety follows an exceptionally stressful life event or a significant life change. While psychosocial stressors may precipitate a wide variety of psychiatric syndromes, they are elsewhere neither necessary nor sufficient to explain the occurrence and form of the disorder. The stress and adjustment disorders, however, are seen as arising as a direct consequence of the trauma or life change.

Dissociative disorder is a group of entities that share a partial or complete loss of the normal integration between memory of the past, awareness of identity and immediate sensations, and control of bodily movements. It is presumed that, in these disorders, the ability to exert conscious and selective control over memory, sensation or bodily function is impaired.

Somatoform disorders are those in which physical symptoms are repeatedly presented with requests for investigation or treatment, in spite of the absence of physical findings to substantiate the perception. Compared with patients who suffer from psychogenic movement or sensory disorders, those with somatoform disorders will demand attention and usually resent physicians who fail to believe in the physical nature of their illnesses. Even when the onset of symptoms is temporally related to a stressful life event, or when external manifestations of depression or anxiety are obvious to others, these patients will frequently resist speculation about psychological causation.

Other neurotic disorders feature two clinical entities, neurasthenia and depersonalization–derealization syndrome. The former, recalling the pre-Freudian nomenclature, is a controversial category in contemporary psychiatry. Its main feature is fatigue, which may occur upon either mental or physical exercise. The diagnosis is to be made only after depressive and anxiety

Table 97.2 Classification of neurotic disorders

ICD-10	DSM-IV
F40 *Phobic disorder*	*Anxiety disorders*
40.0 Agoraphobia	300.21 Panic disorder with agoraphobia
.00 Without panic disorder	300.01 Panic disorder without agoraphobia
.01 With panic disorder	300.22 Agoraphobia without history of panic disorder
40.1 Social phobias	300.29 Specific phobia
40.2 Specific (isolated) phobias	300.23 Social phobia
F41 *Other anxiety disorders*	300.3 Obsessive-compulsive disorder
41.0 Panic disorder	309.89 Post-traumatic stress disorder
41.1 Generalized anxiety disorder	308.3 Acute stress disorder
41.2 Mixed anxiety and depressive disorder	300.02 Generalized anxiety disorder
F42 *Obsessive-compulsive disorder*	*Somatoform disorders*
42.0 Predominantly obsessional thoughts	300.81 Somatization disorder
42.1 Predominantly compulsive acts	300.11 Conversion disorder
F43 *Reaction to severe stress and adjustment disorders*	307 Pain disorder
43.0 Acute stress reaction	300.7 Hypochondriasis
43.1 Post-traumatic stress disorder	300.7 Body dysmorphic disorder
43.2 Adjustment disorder	*Dissociative disorders*
.20 Brief depressive reaction	300.12 Dissociative amnesia
.21 Prolonged depressive reaction	300.13 Dissociative fugue
.22 With predominant disturbance of other emotions	300.14 Dissociative identity disorder
.23 With predominant disturbance of conduct	300.6 Depersonalization disorder
.24 With mixed disturbance of emotions and conduct	*Adjustment disorder*
F44 *Dissociative and conversion disorder*	309.0 With depressed mood
44.0 Psychogenic amnesia	309.24 With anxiety
44.1 Psychogenic fugue	309.40 With mixed disturbances of emotions and conduct
44.2 Psychogenic stupor	309.28 With mixed anxiety and depressed mood
44.3 Trance and possession states	309.3 With disturbance of conduct
44.4 Psychogenic movement disorders	
44.5 Psychogenic convulsions	
44.6 Psychogenic anaesthesia and sensory loss	
F45 *Somatoform disorders*	
45.0 Multiple somatization disorder	
45.1 Undifferentiated somatoform disorder	
45.2 Hypochondriacal syndrome	
45.3 Psychogenic autonomic dysfunction	
45.4 Psychogenic pain	
F48 *Other neurotic disorders*	
48.0 Neurasthenia	
48.1 Depersonalization–derealization syndrome	

disorders have been ruled out. Depersonalization–derealization syndrome is a rare disorder in which the patient feels that his/her own mental activity, body or surroundings are changed in quality so as to be unreal or remote. This phenomenon is more commonly observed as a feature of depression, phobias, obsessive-compulsive disorder and some psychoses.

Special Considerations in Geriatric Patients

Anxiety, both as a symptom and as a disorder, is common among the elderly, but not remarkably more or less so than at other ages. The nature of worry and its clinical manifestations, however, change with increasing age. The intricate relationships among psychosocial stress, physical illness, depression and anxiety in late life make the recognition, diagnosis and classification of neurotic disorders in the elderly quite complex[14–16].

The clinician can usually compare the fears and concerns of a younger patient against those of his/her own peers and arrive at a credible assessment of whether or not the anxieties are pathological. The aged, however have different fears; they worry about physical illness, crime, institutionalization, financial disaster, senility and physical dependency. It is often hard for the younger physician to determine whether the subjective interpretation of events, or the anticipation of future events, is in the realm of clinical anxiety or constitutes adaptive concern. Anxiety results from feelings of vulnerability, and the elderly are truly vulnerable in many ways. It is no easy task to diagnose agoraphobia in an 80-year-old person whose fear of crime in her neighborhood may exceed its statistical likelihood. The clinician walks a fine line between pathologizing a healthy response and failing to recognize neurotic dysfunction[14].

Physical illnesses with psychiatric manifestations increase in prevalence with age, as does the need to take medications with emotional or behavioral side effects. Emphysema, for example, may produce features indistinguishable from those of panic disorder. Hyperthyroidism is commonly accompanied by symptoms resembling those of generalized anxiety disorder. Further, the guiding symptom profiles for the underlying disorders may be absent or muted in the aging person. "Silent myocardial infarction" and afebrile pneumonia are fairly common. Finally, the elderly consume significantly more medication than do younger people and exhibit psychiatric side effects at lower doses and serum levels. Bronchodilators may produce the symptoms of many anxiety states; recommended doses of over-the-counter medications for sleep or colds may induce presentations resembling dissociative states[16].

As could be expected, the diagnosis of somatoform disorders and hypochondriasis is particularly complicated in the elderly. Somatic complaints are common. To some extent, the somatic presentation of emotional disorders is a sociocultural cohort phenomenon. The generation of people over 70 in the 2000s, for example, grew up in the 1940s and earlier. At that time, words such as "depression" and "anxiety" were not commonplace parts of everyday conversation. Emotional introspection was not culturally normative. Thus, the older person who complains today of having "butterflies in my stomach" may be aware of the physical concomitants of anxiety, but not of the emotional state underlying it. The clinician must "translate" somatically-phrased complaints to help determine the affective condition.

Furthermore, the increase in prevalence of almost all physical illnesses with age confounds the determination of pathological perception and behavior, necessary for making diagnoses of somatoform disorders. Both DSM-IV and ICD-10 leave room for a subjective judgment of whether the presence of physical symptoms is sufficient to explain the intensity of the patient's response. There are no objective grounds for deciding when a complaint of abdominal pain constitutes a somatoform disorder in a person with concurrent emphysema, arthritis and congestive heart failure[14,17].

While the delineation of the diagnosis and treatment of post-traumatic stress disorder (PTSD) followed the societal impact of returning Vietnam War veterans, the syndrome is not uncommon in older individuals. The trauma may have been a different war (World War II or Korea), a natural disaster, or a personal event

such as physical assault. Symptoms may occur early and continue for decades. In many cases, symptoms may not even be manifest until many years after the traumatic event. Often, the symptoms of delayed PTSD are precipitated by a psychologically reminiscent contemporary event; a concentration camp survivor may not experience stress-related symptoms overtly until becoming widowed and being institutionalized half a century later[14,15].

SUMMARY

The current classification of neurotic disorders is the most recent step in the evolution of the nosological understanding of a diverse group of syndromes. The ICD-10 grouping represents a compromise between the phenomenological grouping of neurotic conditions on a scale of severity between healthy and psychotic function, and the etiological clustering of disorders presumed to arise from internal conflicts and vulnerabilities to external stressors. The ambiguities inherent in this system reflect the incomplete state of knowledge about the etiologies of the constituent conditions. The North American schema of DSM-IV sets aside questions of etiology, except in the case of adjustment disorders, and relies on ostensibly atheoretical phenomenological criteria.

Although the diagnostic criteria are technically independent of the age of the patient in both systems, aging affects the presentation of many of these disorders and makes clinical diagnosis challenging. The multiple biological and social stressors of late life blur the distinction between "normal" and "pathological" responses to these threats. Physical illnesses, which increase in frequency with aging, may produce clinical symptoms easily mistaken for neurotic anxiety. The prevalence of somatic pathology forces subjective judgments about the presence of somatoform and conversion disorders. Chronic and delayed stress reactions are clinically distinct from the acute forms seen in younger individuals.

The lack of clarity in the classification of these disorders, however, is probably less a manifestation of the shortcomings of the nosological systems than a reflection of the complicated function of the human mind. The neurotic disorders, as well as current science can determine, are a product not of brain disease but of human response to a complicated and stressful world. Simplicity in their nosology would belie the challenges they pose to patients and clinicians.

Epidemiology of Neurotic Disorders

Dan G. Blazer
Duke University Medical Center, Durham, NC, USA

Neurotic disorders are grouped as a special category (the 300 group) in ICD-9[1]. They are mental disorders without any demonstrable organic basis, in which the patient may have considerable insight, and has unimpaired reality testing, i.e. he/she usually does not confuse a morbid subjective experience and fantasies with external reality. Included within the neurotic disorders are anxiety states (both generalized anxiety and panic disorder), hysteria (including conversion reactions), phobic states, obsessive-compulsive disorder, neurotic depression, neurasthenia and depersonalization syndrome.

The Diagnostic and Statistical Manual of Mental Disorders[2] of the American Psychiatric Association, in contrast, does not recognize the neurotic disorders as a distinct entity. Rather, all mood disorders (including the more severe depressive disorders, such as bipolar disorder) are classified in the same category with dysthymia or neurotic depression. Anxiety disorders in DSM-IV include generalized anxiety, panic disorder, phobic disorders and obsessive-compulsive disorders. There is no category within DSM-IV for neurasthenia.

As the epidemiology of the mood disorders will be covered elsewhere, in this chapter current knowledge regarding the epidemiology of the neurotic disorders will be reviewed with especial attention to anxiety. All extant studies that provide useful estimates by age are prevalence studies. Few investigators have concentrated specifically on risk factors by age. In addition, a Medline search of prevalence and incidence studies of generalized anxiety, panic, phobic and obsessive-compulsive disorders in late life since 1996 uncovered only one study. Therefore, the focus of this chapter will be predominantly upon estimates of prevalence of the neurotic disorders by age. Much of the review will feature the Epidemiologic Catchment Area (ECA) studies in the USA.

HISTORICAL REVIEW

At least two early studies provide estimates of the prevalence of neurotic disorders by age. Leighton *et al.*[3], classifying "psychoneurotic" disorders according to DSM-I in the Sterling County study, found that women experienced a peak in psychoneurotic disorders in the 40–49 decade, while the largest percentage of male psychoneurotics were found in the 60–69 decade. For both groups, there was a significant decrease in prevalence in subjects over the age of 70. Pasamanic *et al.*[4] reported an overall prevalence of psychoneurotic disorders of 5.3%. The rates were lowest for subjects under the age of 15 but remained constant through most of adult life. For the 65+ age group, the prevalence estimate was 7%. These investigators of the epidemiology of psychoneurotic disorders found little evidence of an increased prevalence by age but neither did they find evidence for a decrease. In these studies, however, the number of subjects aged 65+ was generally too small to make accurate estimates.

Kay *et al.*[5], in their survey of older persons in Newcastle upon Tyne, which included both institutional cases and those individuals living in the community, found a prevalence of 10.2% for moderate to severe forms of neuroses in older persons. They did not compare the prevalence of neuroses by age. Bergmann[6] found that 11% of a community sample of 300 persons reported developing a neurosis after the age of 60. He also noted the association between neurotic disorders and physical health problems. Each of the above studies aggregated all psychoneurotic disorders and did not exclude depression.

Regarding specific neurotic disorders, few investigators have reported prevalence estimates by age (except for the Epidemiologic Catchment Area studies). The exception is generalized anxiety, one of the more common disorders regardless of age. Murphy[7] and colleagues estimated the prevalence of both anxiety disorders and conversion disorders in individuals less than 45 years of age vs. those 45 years of age and older in the Sterling County study described above. For these estimates, however, they applied diagnostic criteria similar to those used in the third edition of the *Diagnostic and Statistical Manual*[2] rather than the more inclusive category of psychoneurosis. The prevalence of generalized anxiety was 2.9% overall. In males the prevalence was 2.1% under the age of 45 but less than 1% in individuals 45 years of age and older. The prevalence of generalized anxiety in females 45 years of age and older was 2% compared to 6% for those under the age of 45.

Warheit *et al.*[8], in a study of community-dwelling adults in northern Florida, used a self-rating anxiety scale and found that 14.6% of the sample had significant symptoms of anxiety. Blacks, females, the elderly, those in the lower socioeconomic levels and those separated, widowed and divorced actually had the highest scores (in contrast to the ECA study). In a previous study using the Schedule of Affective Disorders and Schizophrenia–Lifetime Version (SADS-L), the overall prevalence of generalized anxiety was 2.5% and was slightly more common in middle-aged and younger women than in older adults.

Copeland *et al.*[9] in a survey of 1070 elderly persons (65+) living in Liverpool, using the Geriatric Mental State (GMS), found the overall levels of neurotic disorders in the elderly to be 2.4%. Anxiety disorder was the most prevalent of the neurotic disorders, with phobic disorder being the second most prevalent (see below). Hypochondriasis and obsessive-compulsive disorders were found in approximately 0.5% and 0.2%, respectively. During a 3 year follow-up[10], the incidence was 0.44%/year. Women were more

Table 98.1 One year prevalence rates (%) of generalized anxiety (different exclusionary criteria) by age. ECA study[12]

Age	Generalized anxiety/no exclusions	Generalized anxiety/ no panic or major depression	Generalized anxiety/no DSM diagnosis
<30	4.83	3.51	2.35
30–44	3.58	2.12	1.46
45–64	3.74	2.81	1.75
65+	2.22	1.92	1.05

	Outpatient use		Inpatient use	
Age	Generalized anxiety (%)	No generalized anxiety (%)	Generalized anxiety (%)	No generalized anxiety (%)
45–64	37.0	52.8	10.3	5.7
65+	53.5	60.8	38.4	12.0

likely to become cases than men. Many cases did remit during the 3 years between interviews, but most original cases continued to experience some symptoms at follow-up.

FINDINGS FROM THE EPIDEMIOLOGICAL CATCHMENT AREA SURVEY

The most detailed estimates of specific neurotic disorders are derived from the ECA surveys in the USA. The National Institute of Mental Health Multi-Site Epidemiologic Catchment Area (ECA) Program was a collaborative study that combined community and institutional surveys of five communities in the USA—New Haven, CT; Baltimore, MD; Durham, NC; St Louis, MO; and Los Angeles, CA. The large overall sample (over 18 000 subjects), coupled with oversamples of older persons in three of the five sites, provided the most comprehensive estimates of the prevalence of specific anxiety disorders among community-dwelling elders from any extant study. The instrument used to establish cases was the Diagnostic Interview Schedule (DIS).

The prevalence of generalized anxiety disorder at three of the ECA sites by age is presented in Table 98.1. The patterns presented hold for both males and females and for Whites, Blacks and Hispanics (although the patterns for male Hispanics are less obvious than for the other age, sex and race groups). In all groups, the prevalence for generalized anxiety is relatively high, but is lower in the 65+ age group than for other ages. Prevalence is presented when the symptoms of generalized anxiety are present, regardless of the symptoms of other disorders, when generalized anxiety is present without evidence of panic or major depression, and when generalized anxiety is diagnosed with no other DIS/DSM-III disorders. The patterns by age are the same regardless. In a study from Liverpool, Copeland *et al.*[9] found the prevalence of cases of anxiety among females 65+ years of age to be 1.52%, yet nearly 16% of males and females were classified as subcases. Generalized anxiety is more frequent among persons with dementing disorders than without.

In a further analysis of the ECA data, the age of onset of generalized anxiety is presented in Table 98.2 for Durham, NC. Virtually all cases of generalized anxiety have their onset before the age of 65 in this community sample. Age of onset is evenly distributed across the life cycle except for individuals aged 65+.

In Table 98.3, the use of inpatient and outpatient general health service, with and without generalized anxiety disorder, are compared by age (persons 65+ years of age and persons 45–64). Older persons are more likely to report use of inpatient physical health services if they report a current episode of generalized anxiety. In contrast, older persons who suffer generalized anxiety are no more likely to use outpatient services. The trend in older persons is similar to trends in younger persons for both inpatient and outpatient use.

In Table 98.4, data are presented on other selected neurotic disorders by age and sex from the ECA study. In most cases, for both sexes, the prevalence of neurotic disorders decreases with age. Age differences in the rates of phobic disorder are not as pronounced as those seen for other disorders. Older persons have the lowest rates of panic disorder of any age group, whereas persons in the 30–44 age group have the highest rates. This trend occurs for Whites and Blacks but not for Hispanics. Not only do older persons appear to experience a lower prevalence of panic disorder in late life currently, they also appear to have a lower lifetime prevalence of panic disorder. This lower lifetime prevalence could be explained by the fact that persons with panic disorders are less likely to reach old age. In addition, the cohort phenomenon, which is described frequently throughout this book (i.e. persons in late life currently have been uniquely protected against a number of psychiatric disorders) may be operative for panic disorders as well. One must also consider, however, the possibility that older persons in these community surveys fail to recall episodes of panic in the distant past because they have not experienced them recently or they may find such episodes embarrassing to report.

Table 98.4 One year prevalence rates (%) of selected neurotic disorders by age and gender

	18–29		30–44		45–64		65+	
Disorder	Male	Female	Male	Female	Male	Female	Male	Female
Phobic disorder[13]	6.5	13.4	6.1	16.1	6.7	11.6	4.9	8.8
Panic disorder[13]	0.6	1.1	6.7	1.9	0.7	1.1	0.04	0.4
Obsessive-compulsive disorder[14]	1.8	2.6	1.9	2.2	0.8	1.2	0.8	0.9
Hypochondriasis[9]							0.5	0.5

Stress, Coping and Social Support

Lawrence R. Landerman and Dana Hughes
Duke University Medical Center, Durham, NC, USA

While a multitude of studies have examined the effects of social and environmental stressors, coping behaviors and social support on psychological distress, relatively little is known about their effects on neurotic disorders in the elderly. The effects of stress, support and coping on depression have been studied extensively in the general population and among those aged 65. A smaller number of studies examines their effects on the anxiety disorders in the general population. Very little work has been done with neurotic disorders as the outcome of interest among older persons. Recent reviewers conclude that the anxiety and panic disorders among the elderly have received little attention and that a systematic examination of the risk factors associated with late-life anxiety disorders has barely begun[1–3]. This is the case despite the fact that they are the most prevalent psychiatric conditions among the elderly, as they are among younger persons. Methodological problems involved with defining and operationalizing the anxiety disorders, disentangling anxiety from depression, and the transience of some symptom states account, in part, for the lack of attention they have received in epidemiologic studies[3,4].

Since the overwhelming majority of relevant studies deal with depression rather than the neurotic disorders, we will use these to examine the rationale and evidence for epidemiologic models linking stress, coping and support to psychiatric symptoms and disorder. Next, we will review a smaller but growing number of studies that have begun to examine whether stress, support and coping affect the anxiety disorders in a manner similar to their effects on depression. Since all but three of these anxiety studies are based on general population surveys rather than samples of the elderly *per se*, we will address the degree to which these studies are consistent with a conclusion that similar effects of stress, coping and support on neurosis are present among the elderly. Finally, we will point out key unresolved issues and the practical implications of the studies reviewed.

STRESS, COPING, SOCIAL SUPPORT AND DEPRESSION

Stress

Stressors refer to life experiences that may be perceived as threatening and/or challenging. They include discrete "stressful life events", such as changes in finances, health or marital status. They also include more enduring or chronic problems with regard to income, health or other areas of life. Reviewers are in accord that there is consistent evidence that stress is associated with an increased risk of psychiatric symptoms and disorder[5–7]. Findings for stress and depression are based on samples of older adults as well as the general population and include prospective studies where stress precedes the onset of symptoms[8–10].

Stressful life events are most likely to have negative health consequences if they are perceived as unexpected and undesirable[5]. Negatively-evaluated changes in health, family and living situations, work and finances have been shown to be strongly and positively related to depressive symptoms and major depressive episodes in the general population and in samples of older individuals[5,11,12]. Chronic stressors include poverty, deteriorated neighborhood conditions and ill health, which have been shown to predict both the onset of depression and the course of recovery[13–17]. While cross-sectional studies show an association between cognitive impairment and depression[4–17], prospective studies report mixed and inconclusive results regarding whether dementia or cognitive impairment are risk factors for the onset or duration of depression[17].

While older persons experience fewer potentially stressful life events[18], they experience a "changing landscape of stressors"[19], and are more likely to experience particular events that are strongly related to psychiatric morbidity[20]. These include poor health and disability, widowhood, and the death of other friends and family members[21,22]. While retirement *per se* is not associated with an increased risk of psychiatric disorder[23], a recent study[24] reports that driving cessation is strongly associated with an increased risk of depressive symptoms. Findings are mixed regarding whether stress associated with caring for a disabled person is a risk factor for depression. Initial studies of those (presumably more distressed) caregivers who sought services found high levels of depressive symptoms. A smaller number of community studies of caregiving and depression report inconsistent results[17].

Coping

Coping refers to steps the individual takes to avoid, solve or minimize the impact of life problems[25]. It serves two functions: problem solving and the regulation of emotions. Different coping strategies can have different consequences for psychological well-being generally, and for the impact of stress on well-being in particular. Rodin[26] contends that solving a problem without help from others may promote well-being by enhancing feelings of self-worth and personal control. Requesting help, on the other hand, may negatively affect well-being by generating interpersonal conflict if those asked are unwilling or unable to provide

assistance[9]. This is especially true for financial help. One's social network is typically made up of persons in similar economic circumstances, whose financial resources may already be limited. There is evidence that most older people value independence and prefer to resolve problems by themselves, rather than depend upon others[27]. Systematic evidence for the impact of specific coping strategies on psychiatric morbidity is presently lacking. The number and variety of possible coping responses, together with the fact that assessments of appropriate coping behavior may vary across situations and social groups, has made research in this area difficult[20].

Social Support

Social support refers to a number of different aspects of social relations and includes: (a) social network: the size, stability, and structure of an individual's network of friends, relatives, and acquaintances; (b) social interaction: the presence and quantity of interaction with network members as well as organizational participation; (c) instrumental support: services and assistance provided by family and friends; and (d) perceived support: subjective satisfaction with one's social relationships and availability of support.

Two alternative models have guided most empirical studies of the relationship between social support and depression. With the "stress-buffering" model, a statistical interaction is hypothesized. The protective effect of support is expected to be at its maximum under conditions of stress and weaker when stress is absent[28,29]. Given the presence of a potentially stressful event or experience, social support is thought to influence the degree to which the situation is appraised as threatening, and an individual's capacity to cope. The impact of stress on depression will therefore be strongest among those lacking adequate support. In the absence of stress, the availability of support is of less importance, and the relationship between support and depression is expected to be weaker. With the "main effect" model of stress, support and depression, high levels of social support are hypothesized to promote mental health at all levels of stress. From this perspective, the effects of stress and support are not interactive—the effect of each does not depend upon the level of the other[30,31].

Reviewers report that the protective effect of support on depression varies across its different dimensions in the general population and among older persons[8,9,20,21]. Perceived support is most strongly and consistently protective for depression. There is also longitudinal evidence that the primary causal influence is from perceived support to depression, rather than the reverse. Findings for the protective effect of network size have been mostly negative. Amount of social interaction is associated with depression in several studies, but not with the onset of depression in longitudinal research. Received support can increase, as well as reduce, the risk of depression[9,12]. Krause *et al.*[9] reason that the receipt of assistance may reflect a failed attempt to solve a problem on one's own, and may be accompanied by hostility and resentment from those providing assistance. Reviewers are also in agreement that most (but not all) studies report a stress-by-support interaction consistent with the stress-buffering models[11,20]. Positive findings for stress buffering are most often present for perceived support, and recent findings suggest that anticipated support—the belief that others stand ready and able to help if called upon—is especially critical, as it promotes effective coping and confidence that a problem can be solved[9,13].

According to Kahn and Antonucci's convoy metaphor for social support[32], the size and composition of one's social network changes over the life course as individuals enter and leave a variety of social roles (e.g. spouse, parent, employee). Social networks change composition later in life in response to changes in one's health and employment, and to impairment and death among one's age peers[20]. For example, retirement can provide time to expand the scope of one's social participation, and even poor health, which limits some relationships, may enhance others as one's support network is mobilized to provide assistance[33]. Findings are mixed regarding whether there is a net decrease in network size and frequency of contact in old age, allowing different reviewers to draw different conclusions. However, there is general agreement that aging is not a time of social isolation, and that most older people have a significant number of relationships[20,33]. Studies of changes in social network and interaction after age 65 report considerable change, characterized by widely varying patterns of gains and losses rather than a trend toward isolation[33]. While it is unclear how these specific changes affect the psychological health of older adults, the notion that old age is a time of psychologically debilitating isolation is clearly not supported.

STRESS, COPING, SOCIAL SUPPORT AND THE NEUROTIC DISORDERS

The proposition that stress, support and coping may affect neurosis is consistent with existing theories that suggest that symptoms of anxiety and panic disorders represent a dysfunctional response to potentially stressful environmental events[10]. While anxiety is adaptive in the face of potentially threatening or unpleasant events, the anxiety disorders are characterized by unjustifiably intense and morbid anxiety and panic[2]. Endler's multidimensional interaction model of anxiety includes situational factors (stressors) and individual characteristics which interact to produce anxiety symptoms and disorder[34]. Relevant individual characteristics include "trait anxiety"—a predisposition to react to stressors generally, or to particular stressors, with dysfunctionally high and persistent levels of anxiety. Individual traits also include differentially effective coping styles and behaviors. One's appraisal and use of available resources, such as social support, is incorporated as part of coping.

There is also reason to expect differences in how stress and support might relate to anxiety as opposed to depression. The anxiety disorders, which include agoraphobia (with and without panic attack), social and simple phobia, panic disorder, generalized anxiety disorder and obsessive–compulsive disorder (OCD), are considerably more complex and diverse than the subtypes of depression. This has led reviewers to call for research that considers these subcategories separately in examining the effects of stress, support, coping and other risk factors[34,35]. The "multidimensional" aspect of Endler's model refers to the proposition that trait anxiety may be stressor-specific. Environmental danger might trigger anxiety only among those predisposed on this trait, while a symptomatic response to a job interview might be limited to those differently predisposed. The implication—that the effect of a stressor on anxiety would be greatly attenuated unless it is estimated separately for those with the corresponding trait anxiety—adds considerable complexity to the stress-support model. A related hypothesis—that stressors dealing with loss (of health, finances or social support) might result in sadness and depression, while stressors involving danger (severe future threat but not necessarily loss) might trigger anxiety—further complicates the picture[36].

Reviewers agree that most studies report a positive association between various stressors and one or another measure of anxiety[34,35,37]. Investigators report both transient and long-term symptoms of anxiety and depression following exposure to

extreme experiences (e.g. combat missions and natural and man-made disasters)[34]. Chronic stressors and stressful life events are also related to anxiety[37,38] and negatively-evaluated stressful events have a stronger impact than the number of events *per se*[4]. Stressors included negative life events, physical decline, poor health, chronic financial stress, occupational stress and loss of a family member. Longitudinal findings show that various stressors precede the onset of anxiety[4,36,39,40] and influence treatment outcome over time[38]. There is also evidence that minor stressors (''daily hassles'') may play a particularly important role in the onset of generalized anxiety disorder[41,42]. Three studies examined the stress–anxiety relationship in elderly populations and report various stressors, including stressful life events, health problems and loss of a loved one to be significant risk factors for phobic disorders, generalized anxiety disorder and the anxiety disorders generally[3,4,43].

Coping style and social support are related to one or another measure of anxiety in prior studies. Panic disorder has been found to be associated with less effective coping strategies in response to stress[44–46]. Those with panic disorder are more likely to use strategies involving escape, avoidance, wishful thinking and help-seeking, rather than focused problem-solving without help. Studies based on age-heterogeneous and elderly samples of the elderly report that external locus of control is positively related to anxiety[3,47]. Compared to others, those with generalized anxiety disorder are reported to perceive the same stressors as more stressful and threatening[35]. Several measures of social support have been found to be associated with anxiety symptoms and/or disorder. These include small network size, marital problems, not having a confidante, and loneliness[3,38,39,48]. In one study, death of a network member was found to affect depression but not anxiety[39]. Another study, which focused on stress-buffering, reports that a stress-by-support interaction effect is present for anxiety but weaker than the corresponding effect for depression[49].

CONCLUSION

While the above studies provide evidence that stress, coping and support affect the anxiety disorders as well as depression, they are limited in number and scope and do not permit any firm conclusions about the specific workings of the stress-vulnerability model derived from depression studies, or the more complex multidimensional model proposed by Endler[34]. This is especially true with respect to the elderly population, where we were able to locate only three relevant studies. The extensive literature on depression suggests that the effects of stress, support and coping on psychiatric disorder do not vary with age. However, researchers have only begun to address this issue with respect to neurosis. We located two studies comparing the effects of stress on anxiety in different age groups. One reported that the effects of different stressors were mostly the same in older and younger populations, while a second reported age differences in the impact of stressful life events[3,4].

Perhaps the most critical gap in the literature reviewed here is the absence of systematic knowledge about differences in the effects of stress, coping and support (and risk factors generally) across the specific subcategories of neurosis. Important in its own right, this information is especially critical if consistent and inconsistent findings across studies using different anxiety measures are to contribute to a cumulative understanding. Only one study has examined the effects of the same measures of stress, coping and support on the specific subtypes of anxiety, and reports that partner loss and poor health more strongly related to panic disorder and OCD, while network size and the exchange of emotional support affect only the phobias[3]. Their cross-sectional data and the specificity of the sample (older adults in Holland) make this study an initial step in what needs to be an ongoing process.

Findings are also sparse and inconsistent with respect to other proposed links between neurosis and the risk factors considered. The hypothesis that anxiety and depression may result from different stressors (threat vs. danger) received support in an initial test[36]. Two subsequent studies report that most stressors affected both anxiety and depression, and that differences which did exist were not consistent with the threat vs. danger hypothesis[38,39]. Endler's proposition[34], that particular stressors may trigger anxiety only among those with a congruent susceptibility, has yet to be examined in representative community samples. While there is evidence that social support is protective for the neurotic disorders, we do not know which dimensions of support are critical, whether support exerts a generalized protective effect or whether stress-buffering is operative. Finally, as discussed in Monroe and Wade[35], substantial co-morbidity between anxiety and depression make it imperative that we examine the role of depression in the relationships of stress, coping and support to anxiety.

While epidemiologic examination of the effects of stress, coping and support on the neurotic disorders is still in an initial stage, the research reviewed here is not without practical import. As Sheikh[2] has observed, potential side effects, drug interactions and non-compliance among the elderly make effective non-pharmaceutical therapies particularly attractive[2]. In this regard, clinicians and researchers have reported that the success of exposure-based treatments for agoraphobia depends in part on the patient's marital relationship, and that including the spouse in therapy can be critical to successful treatment[50–52]. Findings reviewed here—that marital satisfaction is protective for anxiety symptoms in addition to agoraphobia—suggest that attention to the marital relationship may improve psychological and behavioral treatments for other anxiety disorders as well. Findings that other forms of social support are also protective suggest that focusing on relationships in addition to the marital one may also be useful. Additional studies of onset and recovery, which systematically related marital and other social relationships to onset and recovery for specific disorders among the elderly, would be especially useful in this area.

The studies reviewed also have implications at the social structural level. There is strong and consistent evidence that inequalities in education, occupation and income are major determinants of the public's mental health, and that the least privileged members of society are at increased risk for health, financial and work-related stressors, which contribute to both anxiety and depression[37,53]. The well-to-do, on the other hand, are less exposed and have more social and material reserves with which to overcome negative and unpredictable events. Treating mental disorder at the social as well as the individual level involves programs and policies designed to reduce inequality and/or reduce its impact on mental health. Among the elderly, improved coverage for mental health treatment under Medicare and Medicaid would enable the elderly, and particularly those with limited incomes, to obtain necessary and timely treatment[20]. Recognizing health problems as a major risk factor for depression among the elderly, Jorm advocates ''improved geriatric care'' to reduce depression[17]. While findings for the impact of health on neurosis are not nearly so extensive as for depression, poor health is a consistent risk factor for one or another measure of anxiety. In this regard, evidence is accumulating that expanded Medicare coverage for prescription drugs, preventive care and other services typically covered by supplemental private insurance would substantially reduce health problems and disability among older persons, especially those with limited financial resources[54].

Evidence that low income persons enter old age in considerably worse health than others[55] indicates that improving the mental health of the elderly will also require attention to social inequality and its link to physical and mental health throughout the life course.

The subjective sense of trepidation or dread about some future event that can motivate one person to stay at work late to complete an important project, can send another to the hospital with the belief that he/she is going into cardiac arrest. As a normal human emotion, anxiety has adaptive value in helping one prepare for, and possibly avoid, deleterious events. This emotion, however, can manifest pathologically if it becomes excessive, inappropriate or maladaptive. Such morbid or clinically significant anxiety can range from excessive worry about mundane concerns to experiencing intense episodes of fear (panic attacks) for no apparent reason. Clinically significant anxiety is usually manifested by a variety of cognitive, behavioral and physiological symptoms. Table 100.1 lists some examples of these multidimensional features. When assessing such symptoms, the clinician will query the patient with regards to the duration, intensity and course to determine whether the cluster of symptoms meet criteria for any of the specific anxiety disorders.

Over the last two decades, researchers have made great strides in furthering the understanding of the phenomenology, comorbidity and clinical course of anxiety disorders in the general population[1–4]. However, research with the geriatric population is lagging, forcing clinicians to use knowledge gained from studies that more commonly study a younger age group. In addition to utilizing these empirical studies, those treating the anxious elderly must rely mostly on their own observations and anecdotal information, in addition to the "youth-biased" literature base[5]. Some have expressed concern that the diagnosis of anxiety states may be particularly difficult in the elderly because of the frequent co-morbidity of depression or medical illness[6–7]. In addition, concerns are being raised regarding the *Diagnostic and Statistical Manual of Mental Disorders*, 4th edn (DSM-IV) of the American Psychiatric Association[8]. The DSM criteria for the anxiety disorders may not always allow for the correct identification of the anxiety-disordered elderly because many older adults display a tendency to deny cognitive symptomatology and instead somatize their distress[9]. Despite these limitations, analyses of the Epidemiologic Catchment Area (ECA) data (using the DSM-III-R criteria) indicate that anxiety disorders can be diagnosed successfully. Finally, the risk of developing an anxiety disorder does not fade in late life. For example, in a large sample of the 65+ age group, individuals experienced a rather high 6 month prevalence of 19.7% for all anxiety disorders[10].

This chapter presents the clinical features of various anxiety disorders based on the criteria set out in the DSM-IV. A list of the DSM-IV anxiety disorders appears in Table 100.2. Differential presentations and unique features of the anxiety disorders in the elderly will be discussed where appropriate.

PANIC DISORDER WITH/WITHOUT AGORAPHOBIA (PD/PDA)

Panic attacks are acute and discrete episodes of intense anxiety that result as a reaction to some perceived threat (emotional, environmental, etc.). The term "panic attack" is used when an individual experiences an intense and acute reaction to an internal or external cue, lasting between a few minutes and a half an hour. The physiological symptoms can include trembling, accelerated heart rate, sweating, shortness of breath, chest pain, dizziness, nausea and the sense that one is somehow detached from one's surroundings[11]. For example, an individual might have been trapped in a crowd of people entering an underground subway system, and will describe feeling "sick to their stomach" when entering one. Another individual might even report high levels of acute anxiety at the mere sight of the stairs leading to the subway. A clinically significant degree of panic symptoms are documented after a review of the patient's history, revealing recurrent and unpredictable panic attacks that precede at least 1 month spent with anticipated worry over possible recurrence.

Diagnostically, one needs also to consider whether there is the presence of agoraphobia in relation to the panic attacks. Agoraphobia involves the persistent fear of being in a situation that results in a panic attack. Individuals suffering from agoraphobia will commonly stay inside their house all day long to ensure the avoidance of the feared situation. Some of the common examples of frightening situations include being caught in traffic on a bridge or freeway. When comparing young and older adults with panic disorder (PD), one of the factors that can affect the clinical presentation appears to be the age of onset. Phenomenologically, it appears that late-onset PD (LOPD, onset of PD at or after age 55) patients report fewer panic symptoms, less avoidance, and score lower on somatization measures than do early-onset PD (EOPD, onset of PD prior to age 55) patients.

AGORAPHOBIA WITHOUT HISTORY OF PANIC DISORDER (AWOPD)

The literature is scant regarding this relatively rare disorder. Its distinguishing feature from Panic Disorder with Agoraphobia is a fear of being in public places or situations from which escape might be difficult, even though there is the *absence* of a history of panic attacks. There is a possibility that, although these patients may not experience full-blown panic attacks, they might suffer from milder ones with only one or two symptoms (limited symptom attacks). It is thus possible that some of these patients

Table 100.1 Multidimensional symptoms of anxiety

Cognitive	Behavioral	Physiological
Nervousness	Hyperkinesis	Muscle tension
Apprehension	Repetitive motor acts	Chest tightness
Worry	Avoidance (e.g. certain places)	Palpitations
Fearfulness	Pressured speech	Hyperventilation
Irritability	Increased startle response	Paresthesias
Distractibility	Lightheadedness	Lightheadedness
	Sweating	Sweating
	Urinary frequency	Urinary frequency

are presenting with a variant of panic disorder. Multicenter studies suggest that AWOPD, GAD and Social Phobia are commonly co-morbid. Moreover, in general, AWOPD presents with worse global functioning than PD or PDA[12]. This syndrome has not been studied in the elderly.

SOCIAL PHOBIA (SOCIAL ANXIETY DISORDER)

Social Anxiety Disorder (SAD) is defined by a persistent fear in one or more social situations marked by fears of performance, excessive scrutiny or of acting in a way that will be embarrassing or bring shame. Frequently, the fear is that of trembling, blushing or sweating profusely in social situations. Other common concerns are of saying something stupid or ''babbling or talking funny''. Common examples include fears of public speaking, avoidance of dating, parties or other social gatherings. Social phobics typically experience marked anticipatory anxiety if they attempt to enter the phobic situation. SAD is associated with onset in early life—typically manifesting in adolescence. The two distinct subtypes, generalized and non-generalized, trigger different types of symptoms, course of illness, pathophysiology and response to treatment[13]. Although systematic studies of this disorder in the elderly are lacking, epidemiological data[11] indicate that it is chronic and persistent in old age. Common manifestations in old age include the inability to eat food in the presence of strangers and, especially in men, being unable to urinate in public lavatories. It is unlikely that an older adult will seek professional help with these complaints as primary. Although systematic studies of social phobia in older patients are lacking, our clinical experience suggests that eating or writing in public can be exceedingly difficult in older social phobics, exacerbated by the use of dentures or the presence of tremors. It is not uncommon to encounter social phobics who present with symptoms of panic disorder. Evidence suggests that this disorder is quite commonly co-morbid with panic disorder[14].

SPECIFIC PHOBIA (FORMERLY SIMPLE PHOBIA)

The distinguishing feature of this disorder is a marked and persistent fear of a specific object or situation (other than a fear of experiencing a panic attack or a fear of social situations). Typically, the patient experiences immediate and intense distress on encountering the phobic stimulus, and recognizes that the fear is excessive and/or unreasonable. Further, the avoidance or anxious anticipation of encountering the phobic stimulus must interfere with the person's daily routine, occupational functioning or social life, or the individual is markedly distressed about having the phobia. The level of anxiety or fear usually varies as a function of both the degree of proximity to the phobic stimuli and the degree to which escape is limited. Examples of common phobias include fear of animals (dogs, snakes, insects, etc.), closed spaces (claustrophobia), flying or heights. There is

Table 100.2 DSM-IV anxiety disorders

- Panic disorder without agoraphobia (PD)
- Panic disorder with agoraphobia (PDA)
- Agoraphobia without history of panic disorder (AWOPD)
- Social phobia (social anxiety disorder, SAD)
- Specific phobia (formerly simple phobia)
- Obsessive-compulsive disorder (OCD)
- Acute stress disorder (ASD)
- Post-traumatic stress disorder (PTSD)
- Generalized anxiety disorder (GAD)
- Anxiety disorder not otherwise specified (ADNOS)
- Anxiety disorder due to a general medical condition
- Substance-induced anxiety disorder

frequent co-occurrence of Specific Phobia with PD and PDA. In the elderly, especially in urban settings, fear of crime seems to be particularly prevalent in the elderly population (although they are the least likely to be victimized). UK researcher Lindesay[15] looked at elderly phobics and matched them for age and sex to case controls without history of phobic disorders, and found that in the elderly phobic disorders are associated with considerably higher psychiatric and medical morbidity. It also appears that, despite higher rates of contact among the phobic elderly with general practitioners compared to controls, only 1 in 60 of the phobic elderly in this study was receiving psychiatric help. In general, systematic studies of specific phobias are lacking in the older population.

OBSESSIVE-COMPULSIVE DISORDER

Obsessive-compulsive disorder (OCD) involves persistent patterns of thoughts, obsessions and behaviors, compulsions that are performed in an effort to decrease the anxiety experienced as a result of the thoughts. Obsessions are thoughts or ideas that come to a person's mind, frequently during the process of completing a specific task, or that occur during a particular type of situation. For example, sufferers may find themselves washing their hands repeatedly, for hours at a time, as a result of shaking a stranger's hand. The unwanted thought is that they may have exposed themselves to a serious disease. The act of washing in this example is what is referred to as a compulsion. OCD is a disorder that is chronic and often disabling for the individual[16]. Depression and other symptoms of anxiety often accompany the symptoms of OCD.

POST-TRAUMATIC STRESS DISORDER (PTSD)

The distinctive feature of post-traumatic stress disorder (PTSD) is that the individual has experienced, either witnessed or was a victim of, a traumatic event to which they reacted with feelings of fear and helplessness. Examples of such events include those that involve actual or threatened death or serious injury, or other threat to one's integrity, or witnessing an event that involves death or serious injury of another, or hearing about death or serious injury to a family member or close associate. In addition, the individual's accompanying response must have involved extreme fear, helplessness or horror. Other essential features include a number of symptoms that cluster into three categories: (a) persistent *re-experiencing* of the traumatic event; (b) persistent *avoidance of stimuli* associated with the traumatic event and a numbing of general responsiveness; and (c) persistent symptoms of *increased arousal*. Symptoms of re-experiencing include distressing dreams of the event, and intense physical and/or psychological distress at exposure to internal or external cues that

symbolize or resemble an aspect of the event. Symptoms of avoidance and numbing include efforts to avoid activities, people, places, and conversations associated with, or that would arouse recollections of, the trauma. Symptoms of hyperarousal include difficulty in falling or staying asleep, hypervigilance and exaggerated startle response. PTSD usually presents with co-morbid conditions such as depression, panic disorder and substance use disorders. Symptoms must be present for at least 1 month and cause clinically significant distress or impairment in social, occupational or other important area of functioning. Reports of PTSD in elderly Holocaust survivors[17] and among elders who were prisoners of war during World War II[18] indicate that PTSD can be a chronic disorder, continuing into old age. There is some evidence that the intensity of the physiological response to the original trauma may be the most significant predictor of a relatively poor outcome and a chronic course[19]. It also appears that ongoing life stressors may slow the recovery process.

ACUTE STRESS DISORDER (ASD)

Characteristic features of this disorder include the development of anxiety, dissociative and other symptoms that occur between 2 days and 1 month after exposure to an extreme traumatic stressor (such as natural or man-made disasters, rape, combat, assault). The symptoms are identical to those described in PTSD, therefore one should consider PTSD as the diagnostic descriptor after a month has passed.

GENERALIZED ANXIETY DISORDER

The distinctive symptoms of this disorder include intense worry about more than one area of one's life. This concern is accompanied by symptoms including: feeling easily tired, experiencing other physical symptoms, such as muscle tension, having trouble sleeping through the night, difficulty concentrating on a task, and feeling irritable or on edge. These symptoms need to be described as having occurred for at least 6 months and must be accompanied by the sense that one cannot control the feelings of anxiety. Many elderly patients with this syndrome may also present with features of depression, thus making it difficult to distinguish between the two diagnoses.

ANXIETY DISORDER DUE TO A GENERAL MEDICAL CONDITION/SUBSTANCE-INDUCED ANXIETY

The elderly as a group are probably most prone to developing this syndrome due to their high prevalence of medical illness and the relatively common occurrence of polypharmacy. Generalized anxiety and/or panic symptoms are the usual presentations among these patients. Among the more common medical disorders producing symptoms of anxiety are endocrine conditions (e.g. hyper- and hypothyroidism, hypoglycemia), cardiovascular conditions (e.g. congestive heart failure, pulmonary embolism, angina, arrhythmias), pulmonary conditions (e.g. chronic obstructive pulmonary disease, pneumonia) and neurological conditions (e.g. neoplasms, Parkinson's disease). Among the more common substances/medications producing symptoms of anxiety in the elderly are alcohol (intoxication or withdrawal), stimulants (caffeine, sympathomimetics in over-the-counter medications), steroids, thyroid preparations, anticholinergic medications and antidepressants. A thorough history, with an attempt to clarify temporal relationship of symptomatology with the onset of medical illness or the beginning of medication, goes a long way toward resolving the issue.

ANXIETY DISORDER NOT OTHERWISE SPECIFIED

This category includes disorders with prominent anxiety symptoms or phobic avoidance behaviors that do not meet criteria for any specific Anxiety or Adjustment Disorder with anxiety features.

MIXED ANXIETY DEPRESSIVE DISORDER (CATEGORY TARGETED FOR FURTHER STUDY IN DSM-IV)

This category of symptoms is included in the DSM-IV Criteria for Further Study. The essential feature of this proposed disorder is dysphoric mood that has been present for at least 1 month. This mood state must be associated with a minimum of four additional symptoms, such as irritability, worry, sleep disturbance, anticipating the worst, concentration or memory difficulties, and hopelessness. Clinicians working with the elderly have long observed the significant overlap in symptoms of anxiety and depression. In fact, it is quite common to see individuals with a combination of anxiety and depression, although one or both disorders might only be present at subsyndromal levels. Since the distinction between symptoms of anxiety and depression may be particularly difficult to make in older populations[20], this category has the potential for significant clinical utility. Further, making a distinction between a primary anxiety disorder and depression is not only of theoretical interest but also of considerable pragmatic value, since medications used for these disorders may have very different side-effect profiles.

ANXIETY/AGITATION IN DEMENTIA

Dementia patients, whether living at home or in a long-term care institution, commonly display behaviors described as agitation. Agitation is operationalized as verbal or motor activity that is either appropriate behavior but repeated frequently, or inappropriate behavior that suggests lack of judgment. As many as 85% of dementia patients go on to develop disruptive, agitated behavior. Early identification of triggers, including environmental stimuli, medication side effects and the inability to communicate internal needs, can lead to effective treatment and relief for already overburdened caregivers. One of the unique aspects in treating such patients is the need to also assess the health and function of the caregiver, which is frequently compromised due to the immense stress involved in performing the tasks to keep such patients safe and their needs attended to.

CONCLUSION

In summary, it appears that anxiety disorders are characterized by a chronic course, usually lasting into old age. Most of the research in the area of the phenomenology of anxiety disorders has been carried out in younger populations, and generalization to an older population is only extended by implication and a limited number of clinical studies and not on a broad-base of empirical data. Clinicians should keep in mind certain factors that can make assessment of anxiety in the elderly problematic. These include a higher rate of medical co-morbidity, which can confound the clinical picture in this population. In addition, a mixed symptom picture of anxiety and depression can make accurate assessment

and specific treatment difficult at times. Finally, a tendency to deny psychopathology and a preference for somatic expression of distress may make it difficult at times to accurately assess the extent of anxiety. Studies designed to investigate any differential manifestations of anxiety disorders in the elderly are clearly needed.

Prognosis of Anxiety Disorders

Pamela J. Swales[2], Erin L. Cassidy[1,2] and Javaid I. Sheikh[1,2]

[1]*Stanford University School of Medicine, Stanford, CA, and*
[2]*Veterans Affairs, Palo Alto Health Care System, CA, USA*

Anxiety disorders most commonly begin in early adulthood, seem to have a relatively protracted course and usually continue in later age[1]. As expected, relatively scant information exists at present about the prognosis of anxiety in the elderly. Therefore, this chapter will discuss research findings regarding the prognosis of anxiety disorders in the general population and, of necessity, make inferences about outcome in the elderly.

PANIC DISORDER (WITH AND WITHOUT AGORAPHOBIA)

Panic disorder is a common, usually chronic, illness with fluctuating symptomatology, which may be punctuated by periods of partial remission. Age of onset is typically in the mid-20s, but it may also develop in late life[2,3]. Panic disorder is commonly associated with considerable psychiatric co-morbidity including depression, obsessive–compulsive disorder, post-traumatic stress disorder and social anxiety disorder[4,5]. Nearly 50% of those with untreated panic disorder develop co-morbid depression and 43% of these have attempted suicide[6,7]. It is now quite well established that, if untreated, panic disorder may also lead to alcohol abuse[8], increased risk for suicide[7] and, in males, higher than average cardiovascular mortality[9]. Many untreated patients also develop multiple avoidance behaviors (agoraphobia), which are likely to produce serious impairments in social and occupational functioning[10].

Panic disorder rarely resolves without medical intervention[11]. Although both pharmacological and cognitive–behavioral interventions seem to be effective in the short term[11], the long-term effect of these treatments on the natural history of panic disorder is less established. Mounting clinical data favor the SSRIs as first-line treatment for patients with panic disorder. Patients should, in general, be treated for a minimum of 1 year. Those who have experienced previous relapses or who have co-morbid conditions should be considered for long-term therapy[12]. Patients who have more than two episodes should be maintained indefinitely.

OBSESSIVE–COMPULSIVE DISORDER

Obsessive–compulsive disorder (OCD) is a chronic and often disabling anxiety disorder that is characterized by recurring obsessions and uncontrolled compulsions. It often occurs co-morbidly with a number of depressive and anxiety disorders. Persons with obsessive–compulsive disorder often experience significant personal and social morbidity. Additionally, they may have difficulty finishing school, finding and maintaining a job and developing relationships[13].

Obsessive–compulsive disorder has a chronic course, and although symptoms may fluctuate over time, the disorder rarely resolves spontaneously without treatment[14,15]. Until relatively recently, many patients were refractory to conventional pharmacotherapy and obsessive–compulsive disorder was traditionally thought to have poor prognosis. However, of late, advances in both pharmacological and behavioral approaches and their combined use have become effective and important approaches in the management of this disorder. Specific psychopharmacological agents, clomipramine (a tricyclic antidepressant) and the selective serotonin reuptake inhibitors (SSRIs), have proved effective in controlled studies[16,17,18]. Thus, with appropriate diagnosis and treatments, most patients, including the elderly with OCD, will experience benefits and an improved quality of life.

SOCIAL PHOBIA (SOCIAL ANXIETY DISORDER)

Social anxiety disorder, an often-overlooked diagnosis, is characterized by a marked fear of social performance, excessive fear of scrutiny, and fear of acting in a way that will be embarrassing to oneself. Thus, exposure to social or public situations may provoke an anxiety response and be endured under extreme distress. The mean age of onset is 15.5 years and onset after age 25 years is uncommon[19]. Epidemiological data suggest that this disorder is chronic and persisting into old age, with most cases remaining untreated[20].

Social anxiety disorder is responsive to both pharmacological and psychological interventions and the two modalities appear to have complementary strengths. For example, cognitive–behavioral therapy[21] and social skills training have proven value. Pharmacological treatment includes the SSRIs, the monoamine oxidase inhibitors and the benzodiazepines, with the SSRIs as first-line treatment[22,23,24]. Information about long-term prognosis with these treatment strategies is lacking. A limitation of all medications is the substantial rate of relapse observed even after prolonged treatment. However, there appears to be a lower incidence of relapse following discontinuation of CBT[25]. Systematic studies of this disorder in the elderly are non-existent, although our clinical experience suggests that public speaking may seem less frightening, and a phobia such as fear of eating in public may be more bothersome, to the elderly than to younger people.

SIMPLE PHOBIA (SPECIFIC PHOBIA)

Generally, specific fears and phobias may be classified into the following groups: (a) situational phobias (lightning, enclosed

spaces, darkness, flying, heights); (b) animal phobias (spiders, snakes); (c) blood-injury (injections, dentists, blood, injuries). An analysis of Epidemiological Catchment Area data suggests that the onset of social phobia is associated with female gender, low education and never having been married[26,27]. It is difficult to characterize the longitudinal course of simple phobias, principally due to the multiplicity of specific causal stimuli. In addition, individuals with one specific phobia may develop additional phobias or other psychopathology at some point in the course of their affliction.

Exposure and related desensitization techniques are the psychosocial treatments of choice for all variants of specific phobias and promise significant improvement[28]. These strategies also promise effective biobehavioral interventions for older individuals.

POST-TRAUMATIC STRESS DISORDER (PTSD)

This condition is commonly characterized by an acute-on-chronic course of multiple symptoms (e.g. emotional numbing, hyperarousal, hypervigilance, nightmares, avoidance behaviors) after a traumatic event. Most studies suggest that women are not at greater risk for traumatic exposure, but are more likely to develop PTSD when exposed to trauma, especially if experienced prior to age 15 years[29,30]. Intensity of the physiological response to the original trauma seems to be the most significant predictor of a relatively poor long-term outcome[31] (see also comments regarding acute stress disorder). Dissociative phenomena, sensation-seeking/ high-risk behavior, emotional constriction, and drug and alcohol abuse also seem to indicate poor prognosis; in addition, on-going life stressors may slow the recovery process[31]. PTSD is frequently accompanied by obsessive–compulsive disorder, phobias, dissociative disorder, generalized anxiety disorder, panic disorder, depression and substance use disorders[13]. In addition, a number of somatic symptoms such as headaches, chronic pain, irritable bowel syndrome and fatigue, are commonly co-morbid.

There is accumulating evidence that pharmacotherapy is effective for the treatment of PTSD. For example, the selective serotonin reuptake inhibitors have demonstrated significant broad-spectrum effects in all the PTSD symptom clusters. They may be considered as first-line (preferred) pharmacological agents[32]. Other medications that may also be considered, are nefazodone, the tricyclic antidepressants and the monoamine oxidase inhibitors. Psychotherapy can be considered as either an alternative or an additive treatment to medications. Numerous psychotherapeutic techniques can help alleviate symptoms. These include cognitive–behavioral therapy, prolonged exposure, supportive–psychodynamic therapy and stress inoculation training[33].

Symptoms of the disorder are similar across age groups—re-experiencing the trauma, avoidance and hyperarousal—and there is no current evidence that aging affects the development of presentation of PTSD in older individuals. Elderly individuals do not appear any more predisposed to develop PTSD than do younger persons[34]. It is not uncommon for individuals who have experienced trauma (e.g. combat) to experience an exacerbation of PTSD, or for post-traumatic disorder to be reactivated, during later life[35,36]. As with other anxiety disorders, pharmacological and biobehavioral interventions found effective with younger populations can be incorporated into treatment for older adults.

GENERALIZED ANXIETY DISORDER (GAD)

GAD typically has an early onset with an acute-on-chronic course and is associated with increased utilization of medical and mental health services and increased consumption of psychotropic medications[37]. The presence of a co-morbid diagnosis is associated with a worsened prognosis and reduced remission rates compared with those patients with GAD alone[38,39]. Women with GAD are more likely to develop co-morbid conditions (e.g. depression) and the presence of such co-morbidity may reduce the likelihood of remission[40].

Treatments for GAD include both pharmacological and psychological interventions. Efficacy has been reported with buspirone, the benzodiazepines, the SSRIs and venlafaxine[41,42,43]. Cognitive–behavioral therapy (CBT) can be quite effective for this disorder in the short term[44]. Additionally, the benefits of CBT appear to be maintained at long-term follow-up and thus may provide a long-term and cost-effective intervention for GAD[45].

ANXIETY DISORDER DUE TO A MEDICAL CONDITION

This syndrome may be more common in the elderly due to more frequent medical illness. Prognosis depends on the nature and course of the underlying medical condition and its management.

ACUTE STRESS DISORDER

Acute stress disorder describes post-traumatic stress reactions that develop in the first month following a traumatic event. A review of the empirical literature on psychological reactions to trauma suggests that dissociative, intrusive, avoidance and arousal symptoms have often been identified across different kinds of traumatic events[46]. Of those individuals who experience trauma, a minority develops acute stress disorder. However, the literature suggests that a substantial majority of those who meet criteria for this disorder subsequently meet the criteria for ASD[47]. Symptoms with strong predictive power for the later development of PTSD include dissociation, re-experiencing, avoidance, acute numbing, and motor restlessness[48,49]. Therefore, in terms of prognosis, it is important to identify this pattern of reactions and to provide appropriate interventions to minimize their degree and duration.

SUBSTANCE-INDUCED ANXIETY DISORDER

A clinical picture of prominent anxiety, panic attacks, obsessions or compulsions characterizes this disorder. There must be evidence that medication use or substance intoxication or withdrawal are etiologically related to the symptoms. Symptoms must be clearly in excess of those customarily associated with the substance and these must cause clinically significant distress or impairment that warrants independent clinical attention. Once the substance is discontinued, the anxiety symptoms will usually remit within days to several weeks[13]. Symptom resolution is dependent upon the half-life of the substance, the presence of a withdrawal syndrome and other factors such as general health, medical co-morbidities and any psychiatric co-morbidities. For these reasons and the factor of aging, prognosis in the elderly may be more protracted.

CONCLUSION

In summary, it appears that anxiety disorders are characterized by a chronic course, with symptomatology becoming worse during periods of physical and emotional stress. Both pharmacological and psychotherapeutic approaches seem to be effective in the acute or short term. Definitive literature about the longer-term effects of treatments on the natural course of these disorders is still

in progress. Not surprisingly, we know little about the natural course and prognosis of anxiety disorders in old age. Future studies designed to answer these questions are sorely needed.

Acute Management of Anxiety and Phobias

Javaid I. Sheikh[1,2], Erin L. Cassidy[1,2] and Pamela J. Swales[2]

[1]*Stanford University School of Medicine, Stanford, CA, and*
[2]*Veterans Affairs, Palo Alto Health Care System, CA, USA*

Anxiety disorders are among the most common psychiatric conditions occurring in the elderly[1]. Although most of these disorders are of rather chronic nature, acute exacerbations, under a variety of conditions, can produce states of extreme anxiety and agitation that can require immediate attention. For example, patients in treatment for an anxiety disorder may seek an emergency appointment with their doctor/therapist due to a magnification of symptoms. Similarly, in a general hospital a psychiatrist may be called to consult on the management of acute anxiety of an elderly patient on a medical or surgical floor; or a resident may be called upon to evaluate and manage an acutely anxious elderly patient in the emergency room. It is also not unusual for patients with a primary anxiety disorder to present for emergency room services, thinking that they have acute medical problems[2], e.g. patients having a panic attack might fear an impending heart attack and seek medical treatment. Since older anxious patients are more likely to have concomitant medical problems than their younger counterparts, they may require a careful medical evaluation to rule out any organic causes of anxiety[3].

The goal of acute management is relief of marked distress; thus, the treatment approach described here will focus on decreasing patients' symptomatology to manageable proportions as expeditiously as possible. Therefore, treatment approaches for long-term management of anxiety and phobias will be omitted. Further, most situations requiring acute management will necessitate combined pharmacological and psychological interventions. Due to a lack of systematic studies of anxiety management in the elderly, much of our discussion will be based on evidence from studies in younger populations and our own clinical experience.

GENERAL PRINCIPLES OF ACUTE MANAGEMENT

Although acute management of various anxiety disorders may vary somewhat according to the diagnosis, certain guidelines can be useful in a majority of situations. To begin, it is important to remember that during states of extreme anxiety, patients can manifest grossly impaired judgment and might appear to be suffering from a psychotic condition, but a few minutes of questioning will usually clarify the issue. A supportive interaction with the patient is essential to successful treatment. A calm, reassuring manner can be very comforting in itself to alleviate the terror of extreme anxiety. Having a keen awareness of the unique psychosocial issues of the elderly, including retirement, possible deaths of close friends and loved ones and a gradual deterioration of physical functioning, is usually very helpful in developing the initial rapport that will allow the patient to comply with subsequent treatment.

Table 102.1 For patients: understanding your anxiety

- The intense physical symptoms you experience when you are highly anxious are those that are natural to the human body; they are not harmful to you as such. All people have an instinctive "fight-or-flight" response to danger. It is the apparent lack of real danger to you that makes your feelings of fear or anxiety seem so uncomfortable and overwhelming.
- A number of factors may have led to your anxiety experience(s). Your doctor or another clinician may have discussed some of these with you. You may have been given medication to help control your anxiety. It is important for you to take your medication exactly as directed. Anxiety may also be controlled by other methods. Some of these are breathing and muscle relaxation skills, visualization (imagination) techniques, and exposure to anxiety-producing situations with the aid of a therapist. No matter what type of treatment you receive, keep your therapist or doctor aware of any problems, questions or concerns you may notice.
- You and your doctor/therapist will be working together to help you in understanding and controlling your anxiety. In your efforts to cope (deal) with anxiety reactions, it is important to keep in mind that you are not alone. Many people suffer from intense and seemingly overwhelming periods of anxiety. Remember also, "there is light at the end of the tunnel". Anxiety symptoms can be controlled. This may take time, practice, courage and a "stick-to-it attitude", but it is definitely do-able.

Patient education about their condition and various forms of treatment can be especially beneficial to geriatric patients. Patients with an anxiety disorder benefit from a discussion of thoughts, feelings and behaviors with their therapist or doctor, which can enhance rapport and facilitate patient understanding, decrease global anxiety and foster patient compliance. Information that may be provided to patients during acute management of anxiety reactions is included in Table 102.1.

The specific interventions may be pharmacological and/or psychological. Before describing specific treatments for various anxiety syndromes, it will be helpful to review general principles of pharmacological and psychological therapies with older adults.

PHARMACOLOGICAL MANAGEMENT

Common age-related changes in absorption, distribution, protein binding, metabolism and excretion of drugs and their implications have been covered in detail elsewhere in this book, and thus we will only address the relevance of these changes to anxiolytics,

including benzodiazepines, β-blockers and buspirone. For benzodiazepines, the net effect of these changes is usually a relatively higher level of active medication or its metabolites compared to younger people. In addition, an increase in the proportion of body fat with aging may mean that a strongly lipophilic benzodiazepine, such as diazepam, will lead to a much higher accumulation in tissues, compared to less lipophilic drugs such as lorazepam and oxazepam, which are preferable in the elderly[4]. Of the β-blockers, propranolol is the most frequently used. One should note, however, that its adverse side effects are most common in patients over the age of 60, including its potential to cause depression and worsen cardiac failure and bronchial asthma, and its potentially troublesome interactions with various other drugs, such as calcium channel blockers, cimetidine and chlorpromazine[5]. Aging does not seem to significantly alter the pharmacokinetics of buspirone[6]. Appropriate usage of these agents in specific situations will be discussed in later sections.

PSYCHOLOGICAL MANAGEMENT

From a cognitive-behavioral perspective, anxiety can be understood to have three core components: psychological (e.g. cognitions and affects), physiological (e.g. increased heart rate, dizziness) and behavioral (e.g. ruminations, compulsions and avoidance behaviors). When unfounded, severe anxiety initiates and maintains maladaptive functioning and psychological disturbance. How an individual perceives, understands and functions with anxiety can be shaped by such factors as coping mechanisms, personality, social and environmental influences and past trauma. Cognitive-behavioral principles are very effective with a variety of psychiatric symptoms[7–8]. For example, breathing and muscle relaxation training, guided imagery, systematic desensitization, relabeling of anxiety reactions, insight into irrational beliefs and systematic homework assignments are effective interventions that may be utilized during acute presentations of anxiety. During acute management, elders may need a greater amount of reassurance and doctor/therapist contact time than their younger counterparts. Maintenance of such techniques through follow-up sessions will increase the internal support strategies of the patient and decrease the risk for future crises.

Diagnostic Categories Most Commonly Requiring Management

Panic Disorder

There are several management strategies that have shown some degree of success in panic disorder[9]. The therapeutic efficacy of antidepressants in panic disorder and agoraphobia is quite well established. Particularly effective are the tricyclic antidepressant imipramine, the monoamine oxidase inhibitor (MAOI) phenelzine, and the selective serotonin reuptake inhibitor (SSRI) sertraline[10–12]. Due to their rapid onset of therapeutic action, however, benzodiazepines should be considered the mainstay of acute management, as antidepressants usually take approximately 2–3 weeks for their therapeutic effects to take place. Although alprazolam is the most commonly used benzodiazepine in panic disorder[13], clonazepam[14] and lorazepam[13] have reportedly been effective.

Cognitive and behavioral therapies are inextricably intertwined in the acute treatment of panic disorder, with or without agoraphobia. Panic disorder may be managed acutely with breathing and muscle relaxation techniques, examination of cognitive beliefs and a series of progressive behavioral exercises. With therapist-assisted graded exposure beginning even during the acute management phase of treatment, frequent exposure sessions may facilitate the lessening of the anxiety symptoms.

Social Phobia (Fear of Public Speaking, Eating in Public, etc.)

β-Blockers have been shown to be superior to a placebo for treatment of a fear of public speaking or performance anxiety in the general population[15,16]. The espoused mechanism of such therapeutic response is the suppression of peripheral responses of anxiety (e.g. palpitations). We know of no studies or clinical reports that address the effectiveness of β-blockers in the socially phobic elderly; thus, it is hard to say whether this treatment will be equally effective in the elderly. It is also not clear whether a benzodiazepine in low dose (e.g. 0.5 mg lorazepam) will be helpful in encountering the phobic situations.

Office-based social skills training as well as exposure *in vivo* (individual or group treatment) can be very effective[17]. For acute management purposes, teaching a single, generally acceptable "coping strategy" is most useful to patients and can be implemented quite easily in a variety of situations. A skilled clinician may also consider the use of paradoxical intention, visualization and systematic desensitization in acute management interventions.

Specific Phobia (Crime, Medical and Dental Procedures, etc.)

A minority of individuals seek psychiatric treatment for simple phobias, and clinically significant improvement is usually obtained in 75–85% of specific phobias treated[18]. Common fears of older adults include being a crime victim and fears about medical and dental procedures. Although crime rates decrease with age, medical and dental procedures increase, therefore successful management strategies are warranted. We find that low-dose benzodiazepines before the medical or dental procedure in very fearful patients may be helpful in alleviating anxiety and producing better compliance with treatment.

Acute management of most simple phobias can be treated effectively, and with therapy gains maintained, with one (2–3 h) office-based, therapist-assisted exposure session[18]. Effective treatment requires focusing on one phobia-related avoidance behavior per session. Breathing and muscle relaxation techniques can also be quite effective in suppressing anxiety responses in older adults.

Generalized Anxiety

In certain instances, the symptomatology of patients with a generalized anxiety disorder can become extremely severe and may require immediate intervention with benzodiazepines. We recommend replacing benzodiazepines with buspirone and/or cognitive-behavioral interventions, including the range of relaxation exercises, until the acute symptomatology is under control.

CONCLUSION

Principles for the acute management of anxiety in the elderly remain more or less consistent over the range of anxiety disorders, although the contexts in which one is asked to evaluate and manage such cases may vary greatly. The importance of a good history, empathy to the patient's psychosocial situation, and awareness of a possibility of an underlying medical condition cannot be overemphasized. Finally, one needs to be cognizant of

the great individual variation in this group and should be ready and willing to tailor the usage of medications and/or cognitive-behavioral techniques to each patient's special needs.

Psychopharmacological Treatment of Anxiety

John L. Beyer and K. Ranga Krishnan
Duke University Medical Center, Durham, NC, USA

Even though the prevalence of anxiety disorders declines as people age, anxiety disorders still remain the most common psychiatric illness in the elderly[1]. This statistic represents not only the continuation of chronic anxiety disorders into later life for many people, but also the development of new anxiety disorders for others. Loneliness and fear of isolation, diminished sensory and general functional capacities, increased incidence of illness, financial limitations and the prospect of dying often generate considerable anxiety[2]. Elderly patients who recover from a mood disorder often develop persistent anxiety, especially in the morning. An estimated 10–20% of older patients experience clinically significant symptoms of anxiety[3]. Unfortunately, many individuals may never seek treatment, or their anxiety may not be recognized. The result has been a significant undertreatment of a very treatable illness.

This chapter reviews the pharmacologic treatment of anxiety disorders in the elderly. At this time, there is no "perfect" anxiolytic drug for treating the elderly[4,5]. Further, there are significant gaps in the research of anxiety disorders in the elderly, which makes the choice of treatment difficult[6]. This chapter will therefore begin with a review of general considerations a physician must make prior to selecting and starting pharmacologic treatment. A discussion of current pharmacologic options will follow. Classes of medication, rather than specific recommendations for each anxiety disorder, will be reviewed, since research has not clarified primary treatments for most anxiety disorders. Finally, guidelines for the evaluation and selection of pharmacologic treatments are suggested.

GENERAL CONSIDERATIONS

When to Treat

The decision to treat the anxious older patient with medication depends on the severity of the anxiety and the degree to which it interferes with the patient's functioning[7,8]. Anxiety may interfere with social and interpersonal activity in the older patient, resulting in a breakdown of support systems or coping skills. It may worsen cognitive function by decreasing a patient's concentration. Anxiety may also exacerbate physical illnesses or may be an unrecognized consequence of a medical disorder. Anxiety has been related to blood pressure variability and, by extension, to increased cardiovascular risk[9]. The DSM-IV has identified several subtypes of anxiety disorders (Table 103.1) for the general adult population. They are based on the presence of a cluster of symptoms with a characteristic course and treatment. However, anxiety may also present as a symptom of another disorder. Therefore, the first task is to assess the impact of the anxiety symptoms on social and emotional functioning or the severity of a coexisting physical illness.

Differential Diagnosis

The diagnosis of anxiety, as either a disorder or a symptom, is not always apparent. This is especially true in the elderly patient. Elderly patients are often less willing to discuss "anxiety", but may report "anxiety-equivalent" complaints and physical illnesses. Thus a patient may deny being "anxious", but admit to being "jittery", "sick", "uneasy", "flustered", "hot", "restless", "ill", "achy", "agitated" or "bad". Alternatively, the patient may verbalize physical symptoms, such as being "sick to my stomach", or having "heart pain" or "insomnia". These complaints may obscure the true diagnosis or complicate another. The physician must therefore be attuned to what the patient is actually saying.

Further complicating the differential diagnosis is the fact that anxiety may present as a primary disorder (panic disorder, generalized anxiety disorder, obsessive–compulsive disorder, etc.) or a symptom of another primary diagnosis (such as depression, thyroid disease, cardiovascular disease or dementia). There are many conditions that may cause anxiety as a symptom (see Table 103.2); thus, differentiating the source or sources may be difficult. Common medical disorders associated with anxiety as a symptom in the elderly include chronic obstructive pulmonary disease, coronary artery disease, early dementia, major depressive episodes, and medication interactions or withdrawal. Environmental stressors, bereavement or anniversary reactions and experience of medical illness or hospitalizations are also commonly associated with anxiety in late life[10]. Non-prescription medications (especially caffeine-containing products, certain cold

and flu medications, alcohol or nicotine withdrawal, and certain herbal remedies) may contribute to anxiety symptoms.

Adult Studies

Research in the treatment of anxiety disorders for elderly patients is limited. A recent summary of the National Institute of Mental Health Workshop on Late-life Anxiety[6] has highlighted this problem, noting three significant research gaps: (a) little consensus on the "best" approach to measure and count anxiety symptoms, syndromes or disorders in late life; (b) insufficient numbers of studies that examine anxiety among older adults; and (c) limited knowledge of the differences in "early" and "later" onset of various anxiety disorders. These limitations become especially significant in treatment recommendations for elderly patients with anxiety. A recent review of the literature[5] indicated that there are very few controlled clinical trials of medication or psychosocial interventions for anxiety disorders in the elderly. Many of the findings take the form of case reports, case series or open studies. Therefore, treatment decisions for elderly patients are usually extrapolated from the clinical studies of younger mixed-age adult populations and personal clinical experience. For the most part, there is little reason to doubt the applicability of the studies to the elderly patient, yet the clinician should be aware of the limitations of the research, and sensitive to the developing research in this area.

Special Adaptations for the Geriatric Patient

Before prescribing anti-anxiety agents for the elderly, the physician should be aware of the several age-related physiologic changes that may alter drug pharmacokinetics and contribute to increased risk of adverse reactions. These include changes in drug absorption, drug distribution, protein binding, cardiac output, hepatic metabolism and renal clearance[11–13]. In addition, changes in neurotransmitter and receptor function in the central nervous system (CNS) may make a patient more sensitive to psychotropic drugs[14]. In general, the usual starting dose of psychotropic drugs for geriatric patients is roughly one-half of the starting dose for younger adult patients.

PSYCHOPHARMACOLOGIC DRUGS

During the past three decades, a variety of agents have been used for the treatment of anxiety and anxiety disorders with varying degrees of success. These include benzodiazepines, buspirone, tricyclic antidepressants (TCAs), monoamine oxidase inhibitors (MAOIs), serotonin selective reuptake inhibitors (SSRIs), newer mixed-action antidepressants, antipsychotic neuroleptics, β-blockers and antihistamines. Despite the multiple medications available, none are completely safe or completely satisfactory in the treatment of anxiety. Zimmer and Gershon's[15] conclusion that the "ideal geriatric anxiolytic" has yet to be developed still holds true today. Therefore, effective methods of treating anxiety disorders are especially dependent upon thoughtful, comprehensive and accurate assessment of psychiatric, social and medical status, as well as a thorough knowledge of the patient's drug history and medication options.

BENZODIAZEPINES

Since the 1960s, the benzodiazepine class of compounds has been the mainstay of drug treatment for patients with situational anxiety, GAD and panic disorder[16]. They are also frequently prescribed for other indications, such as insomnia, relaxation prior to certain medical procedures, seizures, or agitation in demented patients. In the last two decades, increased attention has been given to the prescription pattern of benzodiazepines in the elderly. Benzodiazepines were prescribed at a much higher rate among elderly patients than in the general population[17]. Epidemiologic data suggest that benzodiazepines may be overused in the general elderly population[18]. This is significant because of the potential toxicity and side effects of benzodiazepines, especially common in the elderly.

Despite their multiple uses, benzodiazepines are usually classified in two groups: anxiolytics and sedative–hypnotics. Currently, seven benzodiazepines are available for the treatment of anxiety. Listed in their order of introduction, they are chlordiazepoxide, diazepam, oxazepam, clorazepate, lorazepam, alprazolam and clonazepam[19]. Prazepam and halazepam, two benzodiazepines previously used for the treatment of anxiety, are no longer available in the USA. The most common sedative–hypnotics are triazolam, temazepam and flurazepam. Commonly used benzodiazepines in the elderly are listed in Table 103.3.

Table 103.3 Commonly used benzodiazepines in the elderly

Generic name	Trade name	Onset of action	Indication	Half-life (h)	Metabolism	Active metabolites	Geriatric dose (mg/day)	Route of administration
Short to intermediate half-life								
Triazolam	Halcion	Fast	Hypnotic	2–5	Conjugation	None	0.125–0.5	Oral
Oxazepam	Serax	Intermediate to slow	Anxiolytic	5–15	Conjugation	None	5–30	Oral
Alprazolam	Xanax	Intermediate	Anxiolytic	6–15	Oxidation	Yes	0.125–3.0	Oral
Lorazepam	Ativan	Intermediate	Anxiolytic	10–20	Conjugation	None	0.5–3	Oral, IV, IM
Temazepam	Restoril	Intermediate to slow	Hypnotic	12–24	Conjugation	None	15–30	Oral
Long half-life								
Chlordiazepoxide	Librium	Intermediate	Anxiolytic	8–30	Oxidation	Yes	5–30	Oral, IV, IM
Diazepam	Valium	Fastest	Anxiolytic	26–53	Oxidation	Yes	2–10	Oral, IV, IM
Clorazepate	Tranxene	Fast	Anxiolytic	30–200	Oxidation	Yes	7.5–15	Oral
Flurazepam	Dalmane	Fast	Hypnotic	64–150	Oxidation	Yes	15	Oral
Klonopin	Clonazepam	Intermediate	Anxiolytic	30–40	Oxidation	Yes	0.25–3.0	Oral

Pharmacokinetics

Benzodiazepines undergo two kinds of biotransformation: oxidation and glucuronide conjugation. Oxidative transformation occurs slowly, giving the drugs a long half-life and producing many active metabolites. Conjugative transformation differs from oxidative transformation in that it occurs rapidly and the metabolic products are pharmacologically inactive. As a general rule, benzodiazepines that are inactivated by conjugation reactions appear to be less likely to interact with other medications. For example, cimetidine has been found to inhibit the metabolism of benzodiazepines that require oxidation, but not benzodiazepines inactivated by conjugation (such as lorazepam or oxazepam). Table 103.4 lists several important drug interactions with benzodiazepines.

Elimination half-lives of benzodiazepines are variable in the elderly. Usually the effects of ultrashort, short and intermediate half-life benzodiazepines do not carry over to the next day when they are used as a sedative[20]. Ultrashort benzodiazepines are generally used to treat insomnia rather than daytime anxiety. They can cause rebound insomnia after abrupt discontinuation. Safety concerns about triazolam (i.e. after being noted to cause confusion, agitation and hallucinations) have led to its ban in several European countries[18]. Benzodiazepines with long half-lives can significantly contribute to increased risk of falls and hip fracture in elderly patients[21].

The onset of action after a single dose is primarily dependent upon the drug's absorption rate. Most benzodiazepines are highly lipophilic. Benzodiazepines that are more lipid-soluble have a faster onset of action because they are absorbed and diffused into central synapses more rapidly[22,23]. This rapid onset of action can produce euphoria and thereby enhance abuse potential.

Table 103.4 Drug interactions with the benzodiazepines

Drug	Effect
Alcohol	Increased CNS sedation
Neuroleptics	Increased CNS sedation
Narcotics	Increased CNS sedation
Antihistamines	Increased CNS sedation
MAO Inhibitors	Increased CNS sedation
Cimetidine	Increased elimination half-life and decreased clearance of alprazolam, diazepam and chlordiazepoxide
Isoniazid	Decreased metabolism of diazepam
Rifampin	Increased metabolism of diazepam
Antacids	Decreased absorption of clorazepate and chlordiazepoxide
Digoxin	Increased digoxin levels
Levodopa	Decreased control of parkinsonism by levodopa
Fluvoxamine	Increased levels of alprazolam

Efficacy

Benzodiazepines are effective for generalized anxiety disorder (GAD). Clonazepam has been shown effective for social phobia. Clonazepam and alprazolam are effective in panic disorder. Efficacy and use in post-traumatic stress disorder (PTSD) is limited. A paradoxical reaction has been documented when some patients with PTSD are treated with benzodiazepines. None of the benzodiazepines appear effective for obsessive–compulsive disorder (OCD).

Dependence and Withdrawal

True physiologic dependence, resulting in a withdrawal and abstinence syndrome, develops to benzodiazepines usually after 3–4 months of daily use[14]. Withdrawal symptoms are likely to be more severe with abruptly discontinued therapy, and with patients receiving short half-life benzodiazepines, or higher daily doses. The symptoms of withdrawal include tachycardia, orthostasis, intention tremors, diaphoresis, hyper-reflexia, anxiety, insomnia, nightmares, malaise, anorexia, headache, muscle pain and twitching, tinnitus, hyperacusis, photophobia, metallic taste, strange smells and, in more severe cases, hyperthermia, nausea, vomiting, delirium, seizures and psychosis.

Side Effects

Although benzodiazepines have been shown to be effective in younger populations, systematic studies in the elderly are lacking. Judicious use is therefore important, since they may have several significant side effects. Adverse drug reactions to the benzodiazepines are almost twice as common in patients over the age of 70 years compared with those aged 40 years or less[24].

Benzodiazepines do tend to produce greater effects on the central nervous system of the elderly than in younger patients[12,13]. This is due partly to increased target-organ sensitivity and partly to altered pharmacokinetics in the elderly (i.e. duration of half-life and peak blood level)[7]. The most common benzodiazepine side effect is a dose-dependent CNS depression. Symptoms include

fatigue, drowsiness, sedation, muscle weakness, blurred vision, nystagmus, dysarthria, ataxia and impaired psychomotor and cognitive performance[12,25,26]. The impairment of motor coordination causes drivers taking benzodiazepines to be five times more likely of being involved in a serious road accident[27]. Cognitive impairment can be severe enough to present as a pseudodementia in susceptible elderly patients.

Benzodiazepines may also cause a paradoxical reaction of restlessness, confusion, irritability and even aggression. Outbursts of anger in elderly patients receiving benzodiazepines may indicate the need to consider an alternative medicine. There are also published case reports of benzodiazepines inducing a secondary mania[28,29]. Benzodiazepines may cause mild respiratory depression in patients with chronic obstructive lung disease. Mixing benzodiazepines with other CNS depressants such as alcohol can lead to severe intoxication or (potentially lethal) respiratory depression.

Selection

In general, benzodiazepines are equivalent in terms of overall efficacy[30]. The selection of a particular benzodiazepine is primarily based upon the patient's particular problem and the medication properties (route of metabolism, length of half-life, onset of action, and presence of active metabolites)[31]. In general, the following guidelines should be considered when using a benzodiazepine:

1. Benzodiazepines that undergo conjugation to water-soluble glucuronides prior to excretion in the urine (e.g. temazepam, lorazepam, oxazepam) have no active metabolites and their pharmacokinetics are not significantly changed by the aging process[32]. They are probably the wisest choice for elderly patients with severely impaired hepatic function.
2. Short (but not ultrashort) half-life drugs are preferable to long half-life medications, since they appear less likely to increase the risk for hip fractures[21].
3. Accumulation of benzodiazepines is directly related to the amount of fat. Therefore, the obese or severely medically frail patients may be at increased risk.
4. Avoid benzodiazepine use in patients dependent on alcohol or other drugs.
5. Begin with lower doses and titrate upwards gradually (“start low and go slow”).
6. Try to limit the length of use to 3–4 months. Taper benzodiazepines over a 4–8 week period.

Buspirone

Buspirone (Buspar) is a novel anti-anxiety agent unrelated to the benzodiazepines in chemical structure or pharmacologic characteristics. Its mechanism of action is probably related to its high affinity for the serotonin type $5\text{-}HT_{1A}$ receptor, which causes reduced serotoninergic activity. In addition, it enhances brain dopaminergic and noradrenergic activity[33,34].

Efficacy

Buspirone is effective in the treatment of generalized anxiety disorder in the elderly. It is well tolerated and as effective as the benzodiazepines[35–38]. However, buspirone does not appear to be effective in the treatment of panic disorder[39]. Some researchers suggest that buspirone may be helpful in mixed anxiety/depression symptoms. It may also be effective as an adjunct treatment for OCD. Its use in PTSD and social phobia appears to be limited.

Administration

Therapeutic doses are in the range 20–60 mg daily; however, buspirone's short half-life (averaging 2–3 h) requires that it be given three times a day (usually with meals). Studies have demonstrated that buspirone may remain effective for at least 6 weeks, although longer efficacy is presumed.

Two major disadvantages of buspirone are the requirement for multiple daily dosing and the lack of immediate effect. Buspirone may take 1–3 weeks at therapeutic dosing before the anxiolytic effect begins. Some researchers have also suggested that the efficacy of buspirone may be reduced in patients who have previously been treated with benzodiazepines[40]. Others suggest using a benzodiazepine for the first 1–2 weeks when initiating treatment with buspirone until it becomes effective.

Side Effects

Buspirone side effects include nausea, headache, nervousness, dizziness, lightheadedness and fatigue. Unlike the benzodiazepines, buspirone does not appear to cause psychomotor impairment, dependence, withdrawal or abuse[41]. Further, it does not interact with alcohol and other sedative drugs. Buspirone lacks hypnotic, anticonvulsant and muscle relaxant properties. Therefore, it may be of particular value in the treatment of patients unable to tolerate the sedative effects of benzodiazepines[42], or patients with a history of substance abuse.

Antidepressants

Tricyclic Antidepressants

Efficacy. Tricyclic antidepressants (TCAs) have been shown to be effective in treating mixed anxiety–depression states, panic disorder and generalized anxiety disorder in the elderly[43–46]. In the general adult population, TCAs are frequently used in PTSD and clomipramine has been approved by the FDA to treat OCD. However, the overall use of TCAs has decreased as other options (especially the SSRIs) have become available. This is primarily due to the significant side effects TCAs have at therapeutic doses that also increase the risk to physically ill patients and potentiates toxicity in overdose. Further, like all other medications used for the treatment of anxiety (except the benzodiazepines), TCAs usually require several weeks to show maximal benefit. Despite their shortcomings, tricyclic antidepressants remain an alternative treatment for GAD[47].

Side Effects. Common side effects may be mediated by α-adrenergic blockade, anticholinergic effects and antihistaminergic effects. The α-adrenergic blockade of TCAs may cause significant orthostatic hypotension or cardiac conduction irregularities. The elderly are particularly susceptible to injury from orthostatic falls. Patients with complete heart block should not be given TCAs because these medications can cause a prolonged QRS complex. Trazodone, a heterocyclic antidepressant, is sometimes used as a sedative or in the treatment of agitation for demented patients, but the side effects of postural hypotension may limit its use[20].

Anticholinergic side effects of TCAs are dry mouth, blurred vision, constipation, urinary retention and confusion or even psychosis. This may be particularly significant in patients with

Alzheimer's disease or other disorders that impair memory. The major antihistaminergic effect is sedation.

Guidelines for Use. Imipramine and amitriptyline have long been established in the adult population for use in various anxiety disorders. However, their tertiary amine structure tends to cause increased anticholinergic, adrenergic and sedative side effects. The secondary amines, nortriptyline and desipramine, are preferred for use in the elderly due to their less intense side effects. In general, anxiety disorders appear to respond at doses lower than those used in mood disorders. A baseline EKG is highly recommended prior to starting therapy, since TCAs can cause a prolonged QRS complex.

Monoamine Oxidase Inhibitors (MAOIs)

Monoamine oxidase inhibitors have been effective in treating mixed anxiety–depression and panic disorder but not pure generalized anxiety[44,45]. MAOIs are rarely used now because of their potential side effects (especially the drug–diet interactions) and the wider availability of newer antidepressant choices. Phenelzine and tranylcypromine are the MAOIs of choice for the elderly in the USA[8]. Interestingly, phenelzine was found to be more effective in the elderly than in younger patients[44], and just as well tolerated as nortriptyline[48]. The starting dose is 15 mg daily in the morning, increasing by 15 mg every few days to an average dose of 45–60 mg[49]. Moclobemide, a reversible MAOI available outside the USA, is effective in social phobia and panic disorder[50,51].

Orthostatic hypotension is the major side effect of MAOIs; however, the major concern is the possibility of an acute hypertensive crisis due to the drug and dietary interactions.

Selective Serotonin Reuptake Inhibitors (SSRIs)

Efficacy. The introduction of SSRIs has transformed the treatment of both depression and anxiety in the adult population. Five SSRIs are now available for use in the USA: fluoxetine, sertraline, paroxetine, fluvoxamine and citalopram. Since their introduction, certain SSRIs have obtained indications for the treatment of not only depression, but also panic disorder, bulimia, OCD and social phobia. They are also used in the treatment of PTSD and GAD. Still, as with the other medications, the treatment of geriatric patients is primarily extrapolated from studies of younger adults. Case reports, open trials and some controlled studies in elderly patients have been completed in the elderly population. Fluoxetine has been shown to be effective in treatment of geriatric depressed patients with agitation[20]. Fluvoxamine and fluoxetine have been shown to be effective in clinical trials for OCD that have included some elderly patients[52,53]. Case studies have shown sertraline, paroxetine, venlafaxine, fluoxetine and fluvoxamine effective in social phobias and anxiety[54–57].

Side Effects. All SSRIs can cause gastrointestinal effects (nausea and diarrhea), sexual arousal and performance changes, and a decrease in appetite and weight. The nausea and diarrhea are usually dose-dependent and resolve for most patients within the first week of treatment. An increasing concern has been SSRI-associated weight gain, seen with extended use. Paroxetine has been noted to have some anticholinergic activity that may be more apparent in elderly, sensitive patients. A significant potential side effect of SSRIs includes a tendency to stimulate patients, causing tremor and jitteriness.

Guidelines for Use. Since some SSRIs have been associated with "activation" and worsening of anxiety, some clinicians have suggested avoiding them as an initial choice for treatment[20]. Smith and colleagues[58] have recommended that SSRIs that have shorter half-lives and are less activating, such as paroxetine or sertraline, be used preferentially to fluoxetine. However, it should be noted that fluoxetine has been shown to be effective in treating anxiety symptoms associated with depression. Because of the interaction between cytochrome P-450 and drug metabolism, caution should be used when combining SSRIs with tricyclic antidepressants, antiarrhythmics, codeine, carbamazepine, benzodiazepines, and β-blockers or calcium channel blockers.

Newer Antidepressants

Nefazodone offers promise as a useful antidepressant for depressed elderly patients who have concomitant anxiety symptoms[20]. It has an acceptable level of daytime sedation for the elderly[59], but minimal anticholinergic and other side effects. Its more moderate serotonin reuptake inhibition may make it less likely to create agitation than the SSRIs[60]. Nefazodone does inhibit P-450 isoenzymes and is contraindicated for use with terfenadine, astemizole and cisapride. It will also increase the plasma levels of alprazolam, midazolam and triazolam.

Venlafaxine, a newer antidepressant that enhances both norepinephrine and serotonin activity, is increasingly being used to treat depression and anxiety in the general adult population[61]. It is approved for the treatment of GAD. Its side-effect profile is similar to the SSRIs. Small elevations in blood pressure may be seen at dosages above 200 mg/day.

Mirtazapine is the first of a new class of antidepressants, the noradrenergic and specific serotoninergic antidepressants (NaSSA). In trials for antidepressant treatment in the general adult population, mirtazapine has shown beneficial effects on the concomitant symptoms of anxiety and sleep disturbances[62]. It has few anticholinergic, adrenergic and serotonin-related adverse effects, but can be very sedating due to the antihistaminergic effects. There is no current data on its effectiveness in the elderly.

Neuroleptics

Neuroleptics are often useful for treating severe agitation associated with psychosis, delirium, and dementia[63]. The newer antipsychotics such as olanzapine and risperidone are especially being used in the treatment of refractory anxiety in the context of dementia. However, the use of neuroleptics for the treatment of subjective anxiety states, especially in the elderly, has never been demonstrated[7]. It is important to remember that neuroleptic drug side effects, such as sedation, extrapyramidal reactions, orthostatic hypotension, anticholinergic effects and tardive dyskinesia, can have potentially devastating consequences in older people. Even the newer antipsychotic agents have significant side-effect profiles. Therefore, neuroleptics should not play a significant role in the treatment of anxiety disorders in the elderly.

β-Blockers

The usefulness of β-blockers for treatment of anxiety in the elderly is unclear, since the data for the elderly are restricted to clinical case reports[31]. β-Blocking agents have been shown to be specifically beneficial in younger patients with predominantly somatic symptoms associated with generalized anxiety or anxiety related to stressful situations[64]. They may also have potential use in the treatment of aggression and agitation in patients with

organic brain disease[65]. Although β-blockers decrease autonomically mediated symptoms such as diaphoresis, palpitation, tremor and gastrointestinal upset, they usually do not reduce the inner subjective effects[2,4].

Propranolol in small doses (e.g. 5–10 mg one to four times a day) may be effective in elderly patients[20]. These drugs should not be used in patients with chronic obstructive pulmonary disease, congestive heart failure, heart block, insulin-dependent diabetes, severe renal disease or peripheral vascular disease.

Antihistamines

Sedating antihistamines such as hydroxyzine and diphenhydramine hydrochloride are sometimes useful for anxiety or insomnia in the elderly. They have been rarely recommended because they are less effective than benzodiazepines, and their anticholinergic side effects are outweighed by their weak anxiolytic effects[4]. They may be used in patients with mild symptoms, in severe chronic obstructive pulmonary disease, addiction-prone personalities, alcoholics, or patients for whom more traditional drugs are not effective[66]. However, physicians must be aware that the elderly patient is much more susceptible to their anticholinergic properties, which may cause blurred vision, tachycardia, dry mouth, urinary urgency, constipation, restlessness, hallucinations and confusion. Antihistamines have no potential for inducing drug dependency or addiction.

GENERAL GUIDELINES

Despite the limited data on treatment of anxiety disorders in the elderly, the clinician can successfully treat patients with a conservative and thoughtful use of medications. The following guidelines have been adapted from Small[20].

1. Conduct a complete psychiatric evaluation. Listen specifically for expression of anxiety. Does this patient have anxiety that significantly affects their quality of life or functioning?
2. Consider the full differential diagnosis. Does the pattern of anxiety identify itself as a formal anxiety disorder, or as a symptom of another psychiatric or medical disorder? Geriatric psychiatry has been called "the specialty of co-morbidity". There may be several potential etiologies for anxiety symptoms that should be considered before initiating treatment.
3. Consider non-pharmacologic treatments first. Education and reassurance are invaluable in the treatment of anxiety, and may themselves be adequate treatments. Specifically address social stressors and evaluate the effectiveness of the support systems. Attention to family caregivers may facilitate the positive response to other treatment. Remember, the ability to benefit from therapy is not based on age.
4. Minimize polypharmacy. In the geriatric population (especially those in the nursing care facilities), the use of multiple medications is the rule rather than the exception. Most clinicians stress the importance of reviewing the medication list for potential areas of reduction, prior to adding new treatments. Reducing the number of medications may actually treat the anxiety symptoms[20].
5. When selecting an anxiolytic, consider the full presentation rather than just the anxiety when selecting an initial medication. For example, use an antidepressant if depressive symptoms are apparent. Avoid anticholinergic medications in patients with dementia. Avoid benzodiazepines when the patient's ability to ambulate is compromised.
6. As far as possible, make medication changes one at a time in order to clarify whether a complaint results from a medication side effect or an underlying illness.
7. "Start low and go slow".

Obsessive–compulsive Disorder

James Lindesay
University of Leicester, Leicester, UK

Although obsessive–compulsive disorder (OCD) is known to occur in old age, studies are few and information is limited. This may be because it is often not perceived as a disorder of late life. The mean age of onset is 20–25 years[1–3] and it is unusual for OCD to have its first onset after the age of 50 years. However, OCD is a chronic disorder if untreated, and a significant proportion of cases persist into old age, when they may present to services for the first time. It is important, therefore, that old age psychiatrists are aware of this disorder and of its management.

CLINICAL FEATURES

Diagnostic Criteria

OCD is characterized by intrusive, persistent obsessive thoughts, images or impulses and/or compulsive behaviours that are a significant source of distress, or interfere with the patient's personal or social functioning. The current diagnostic criteria, as set out in DSM-IV[4] and ICD-10[5], apply to all patients, irrespective of age. The limited evidence available indicates that the clinical features of OCD in elderly patients are very similar to those of younger adults. In their comparative study, Kohn *et al.*[6] found that concerns about symmetry, need-to-know and counting rituals were less common in elderly patients, and hand-washing and fear of having sinned were more common, but otherwise there were few differences in clinical features compared with younger OCD patients. Extreme ego-syntonic religiosity has been proposed as a variant of OCD that may be more common in older patients[7].

Differential Diagnosis

Unpleasant, intrusive thoughts and abnormal stereotyped behaviours occur in other mental disorders, and OCD is not diagnosed if their content is *exclusively* related to another disorder, e.g. guilty preoccupations in depression, worries in generalized anxiety, concern with illness in hypochondriasis, weight control in anorexia or avoidance in phobic disorders[4]. It should be borne in mind that conditions such as depression, generalized anxiety and substance abuse may be co-morbid with OCD. In elderly patients, increased anxious orderliness may be a prodrome of dementia; however, this behaviour is not resisted or associated with the tension that occurs in OCD. The compulsive behaviours of OCD resemble the stereotyped behaviours that occur in certain other disorders, such as Tourette's syndrome, Sydenham's chorea, encephalitis and partial complex seizures. Tourette's syndrome and OCD commonly co-occur[8], and patients with OCD may have a history of Sydenham's chorea in childhood[9].

Despite its similar name, obsessional personality disorder is quite distinct from OCD. It is characterized not by obsessions and compulsions, but by a preoccupation with orderliness, perfection and control dating back to early adulthood[4]. In some individuals, there is an inability to discard personal possessions, which may present as the so-called "senile squalor" syndrome after a lifetime of accumulated rubbish.

Not all patients with OCD have insight into the irrationality and inappropriateness of their obsessions and compulsions. If the obsessional thoughts are held with delusional intensity, an additional diagnosis of delusional disorder may be warranted. The ruminative delusions and stereotypies of schizophrenia are usually not ego-dystonic, and therefore would not be regarded as OCD[4].

Clinical Assessment

An effective treatment plan for OCD requires a detailed clinical assessment. What exactly are the main problems? What, if anything, exacerbates or improves the symptoms? How long has the condition been present, and how has it evolved since its onset? What treatments, if any, have been tried in the past? What other symptoms or disorders are present? Any concomitant depression, mania, psychosis or alcohol dependency will require specific management before behavioural treatments for OCD can be effective. If the patient is cognitively impaired, this will have implications for the choice of treatment; for example, some behavioural strategies will not work if information cannot be retained or recalled. In elderly patients with OCD of recent onset, it is important to investigate carefully for any underlying cerebral disease. Late-onset cases are associated with frontal dysfunction[10], which may be caused by a variety of focal and generalized disorders, including cerebrovascular disease, tumours and primary neurodegenerative dementias. Late-onset OCD may also be the result of external factors, such as adverse life events and exposure to trauma, that weaken an elderly individual's resistance to long-standing subclinical obsessionality[11].

EPIDEMIOLOGY

Most of our knowledge about the epidemiology of OCD in old age derives from the US National Institute for Mental Health (NIMH) Epidemiologic Catchment Area (ECA) Program. Overall, the 1 year prevalence for those aged 65 years and older was

0.85% (men 0.75%, women 0.93%), as opposed to 1.65% for the sample as a whole[12]. A more detailed analysis of the elderly population at the Eastern Baltimore site found prevalence rates of 1.3% for those aged 65–74 years and 0.6% in those aged 75+[13]. Following the second wave of the ECA, annual incidence rates were estimated. In males aged 65+, the incidence rate of OCD was one-third of that for males of all ages, but in females there was a non-significant upturn in the incidence rate after age 65[14]. In common with a number of other psychiatric disorders, the lifetime prevalence of OCD decreased with age in this study. The reason for this is unclear, but it may be the result of cohort effects, differential mortality or age-specific differences in symptom ascertainment and recall.

AETIOLOGY

Genetic factors play an important role in the aetiology of OCD; it occurs in 40–50% of parents, 19–39% of siblings and 16% of children of probands with the disorder[15]. Just what is inherited is not clear; other anxiety disorders are also more common in the families of OCD probands[16]. Most of the evidence from clinical, neuropsychological and neuroimaging studies implicates the basal ganglia and their connections with the thalamus and the cerebral cortex in the aetiology of OCD[17]. Specifically, it has been proposed that there is dysfunction in a neuronal circuit involving the orbitofrontal cortex, the basal ganglia, the substantia nigra and the ventrolateral pallidum[18]. The specific response of OCD to serotonin (5-HT) reuptake-inhibiting drugs (see below) suggests that serotonergic neuronal systems are involved, directly or indirectly. In the cognitive-behavioural model of OCD, obsessions and compulsions result from pathological, anxiety-provoking over-control of normal intrusive cognitions[19].

TREATMENT

There are no randomized, controlled trials of treatment of OCD in elderly patients. Accordingly, the guidelines that follow are based upon case reports and extrapolations from studies in younger adults[20].

Non-pharmacological Treatments

Behavioural therapy, in the form of exposure and response-prevention (ERP), is well described as an effective intervention for OCD in younger adults[21]. This involves exposing the patient to the feared situation, and helping him/her to resist the urge to perform the compulsive behaviours that would normally follow this exposure[22]. ERP is least effective in those who have obsessional thoughts and covert rituals unaccompanied by compulsive behaviour. In these patients, a cognitive approach directed at modifying the misinterpretation of intrusive thoughts is more appropriate[23]. There have been a number of case-reports of effective behavioural interventions with elderly OCD patients[19,24–27], but most are difficult to interpret because of the concomitant administration of medication. In the case described by Calamari *et al.*[27], significant improvement following ERP was maintained without medication at 8 month follow-up.

Freud proposed that obsessional symptoms were a regression to a pregenital anal–sadistic phase of development. However, despite this and subsequent psychodynamic formulations of the disorder, there is no evidence that psychodynamic psychotherapy is an effective treatment for OCD at any age.

Pharmacological Treatments

Studies in younger adults indicate that 30–60% of patients with OCD show improvement on appropriate medication, and that drug treatment appears to be more effective for obsessional thoughts than for compulsive behaviours. In practice, drug treatment and behavioural therapy are often given in combination.

The theory that OCD is a disorder of serotoninergic function is based upon the empirical observation that it can be effectively treated by drugs that inhibit serotonin reuptake. Clomipramine is the most extensively studied drug treatment for OCD, and its effectiveness has been established in a number of double-blind placebo-controlled trials in younger adults[28]. However, the lack of receptor sensitivity means that it has significant anticholinergic and antihistaminergic side effects that limit its usefulness in elderly patients[29]. In this age group, the drug of first choice is one of the specific serotonin reuptake inhibitors (SSRIs). Fluoxetine, paroxetine and fluvoxamine are currently licensed in the UK for the treatment of OCD, although none of the trials supporting this indication specifically involved elderly patients. The effective dose for the treatment of OCD with these drugs tends to be higher than that required to treat depression, and the time taken to respond is typically much longer: 10–18 weeks. Studies suggest that long-term therapy is required, as discontinuation of medication leads to relapse of symptoms.

There is little evidence for the effectiveness of other drug treatments in OCD. There are some case reports suggesting that monoamine oxidase inhibitors (MAOIs) may be useful in patients with concomitant panic or severe anxiety. Anxiolytic drugs may also help with the anxiety associated with OCD, but do not appear to have any effect on the core symptoms. A possible exception is buspirone, which may augment the effect of fluoxetine[30,31]. Lithium augmentation of fluoxetine has also been reported as effective in one elderly case[32].

Physical Treatments

There is very little evidence to suggest that ECT is effective in the treatment of OCD in patients who are not also depressed[33]. Some good results have been reported for stereotactic neurosurgical procedures in patients with severe and treatment-refractory illness, including elderly subjects[20], but since negative outcomes are rarely described, this evidence is difficult to interpret.

CONCLUSIONS

OCD may present for the first time in old age, and many elderly patients with chronic illness will not have been exposed to the full range of pharmacological and cognitive-behavioural treatments that are now available. It is important that old age psychiatry services are aware of these treatments and develop some experience in their delivery. There is some evidence that they are effective in elderly patients, but further research is needed. Patients with a new onset of OCD in late life need careful assessment to exclude underlying organic brain disease.

Hypochondriacal Disorder

Andree Allen[1] **and Ewald W. Busse**[2]

[1]*Dorothea Dix Hospital, Raleigh, NC, USA,*
and [2]*Duke University Medical Center, Durham, NC, USA*

The term "hypochondriasis" has its origins in the ancient Greek language. Anatomically, the hypochondrium refers to that part of the body between the ribs and the xiphoid cartilage. The ancient Greeks believed that this part of the body, especially the spleen, was the seat of morbid anxiety about one's health, depression, bad mood and simulated disease[1,2]. This old theory has not withstood the passage of time, but the term "hypochondriasis" has survived and is part of our modern diagnostic nomenclature[3–5]. Hypochondriasis has joined the ranks of syndromes known as somatoform disorder in DSM-IV, with the following diagnostic criteria:

1. The predominant disturbance is preoccupation with the fear of having or the belief that one has a serious disease based on the individual's interpretation of physical signs or sensations as evidence of physical illness (do not include misinterpretation of physical symptoms of panic attack).
2. Appropriate physical evaluation does not support the diagnosis of any physical disorder that can account for the physical signs or sensations or the individual's unwarranted interpretation of them, and the symptoms in (1) are not only the symptoms of panic attacks.
3. The fear of having, or the belief that one has, a disease persists despite medical reassurance.
4. The duration of the disturbance is at least 6 months.
5. The belief in (1) above is not a fixed delusion, as in delusional disorder, somatic type.

There are issues regarding hypochondriasis as a diagnostic entity. Some clinicians and the *International Classification of Diseases* regard it as a specific non-psychotic psychiatric disorder, while others hold that it is a syndrome (a collection of similar symptoms that occur together but are of multiple etiology). It is evident that hypochondriacal symptoms may be part of another disorder, such as a mood disorder or a defense mechanism, as well as a character trait. Starcevic[6] has dissected the hypochondriacal syndrome into potentially useful constructs that represent a stepwise progression. The "hypochondriacal core", as the preoccupation with bodily sensations and functioning, gives rise to a state of "somatic uncertainty", an insecurity feeling resulting in intense anxiety which is poorly tolerated by the individual. This leads to the "disease suspicion", which represents the fear of having a disease. "Hypochondriacal behaviors" ensue as the patient obsessively seeks a medical work-up to uncover the cause of his/her symptoms and is generally dissatisfied, as it is found that there is either an absence of physical disease or that the symptoms are out of proportion to the pathology. Starcevic points out that the hypochondriacal syndrome is a heterogeneous entity with varying degrees of bodily preoccupation, fear, suspicion and a variety of complaints.

Hypochondriasis, with its state of uncertainty, may be seen as a feature of an anxiety disorder. It may be part of a mood disorder, such as a masked depression, where the patient will deny feeling depressed but respond to antidepressant medication. Starcevic[6] makes the point that hypochondriasis may be incorporated into a long-standing, maladaptive pattern of functioning and that many personality disorders may have a hypochondriacal manifestation. There is a fine line to be crossed when the disease suspicion turns into "disease conviction" and the syndrome is no longer hypochondriasis, but a psychotic disorder, such as paranoid delusional disorder, paranoid schizophrenia or major depression with psychotic features.

In his 1987 review article on the subject matter, Lipowski[7] considers that predisposing factors such as genetics, developmental learning, personality and sociocultural environment play a role in hypochondriasis. Swedish investigators have gathered data from adoption studies in regard to familial somatization patterns. The subjects of their studies were drawn from 912 women born out of wedlock in Stockholm, Sweden, during 1930–1949. Between 1965 and 1973, the medical records of 859 subjects were reviewed for duration and number of sick leaves, chief complaint and diagnosis[8–10]; 144 were found to be somatizers. This study suggests that somatization is more common in adopted women than in non-adopted women. This raises the issue of genetic predisposition to somatization, as adoptees are known to have a higher percentage of biological parents with alcoholism and criminality compared to non-adoptees. There may be a complex interaction between the type of somatizers, alcoholism and antisocial behavior and sex differences. The interaction between biological predisposition and environmental influences requires additional attention.

Theories that conceptualize the genesis of hypochondriasis to learned behavior from childhood sound intuitively correct[11]. Children who grow up in families where a serious or chronic illness is present, or who are exposed to a hypochondriacal relative, may well learn a way to obtain attention, sympathy and support, or get the message that physical complaints are acceptable, while complaints of emotional distress are not. Children suffering from physical disorders may get anxious attention from parents. They may also learn that being sick is to avoid unpleasant duties. Somatization may serve as a way

to deal with adverse social situations and to maintain self-esteem.

Kanner[2] felt that hypochondriacal attitudes in children often reflected school problems or "unhappiness at home". He observed that some mothers focused on their child's somatic functioning rather than their own, thus teaching the child to somatize. This improper maladaptive coping pattern may well continue in adulthood. While it is possible that these early childhood influences shape the child into a hypochondriacal character, it may not necessarily follow. There may be innate personality characteristics that predispose to somatization. Barsky and Klerman[5] pointed out that there are individuals who "amplify body sensations", focus on them, misinterpret them and reach the conclusions that they may indicate disease. Costa and McCrae[12] point out that somatizers tend to score highly on measures of neuroticism.

Predisposing factors appear by no means to be solely affected by stressful life events in childhood. In his studies on elderly hypochondriacs, Busse[13] has noted that contributing factors include recurrent exposure to criticism where there is no possibility of escape, reduction in economic status, loss of spouse and friends, isolation due to socioeconomic factors and deterioration in marital satisfaction.

As Lipowski[7] notes, sociocultural factors, such as linguistic habits, health beliefs and inhibition of expression, may play a role in somatization.

EPIDEMIOLOGY

While hypochondriasis is seen throughout the life cycle, it is the most frequent somatoform disorder in the elderly. One epidemiologic study[14] shows that 15% of the elderly in the community over the age of 65 reported perceiving that their physical health was poorer than their actual health status. Other investigators[15] have collected data on adults, but not necessarily exclusively in the elderly. Kellner and Sheffield[15] found that 60–80% of physically healthy individuals in the community had at least one physical complaint in 1 week. In their review of the prevalence of "functional complaints" in primary health care, Barsky and Klerman[5] show that a large proportion of patients (30–80%) who present to the doctor's office do not have evidence of significant physical disease. In their report of the Piedmont Epidemiologic Catchment Area (ECA) study, Swartz *et al.*[16] suggested that somatization symptoms are more prevalent in the rural than in the urban community, that somatization increases with age up to age 65, then tends to drop off, but still remains higher in the elderly over 65 than the age group 18–44. Interestingly, between the ages of 45 and 64, an increase in somatic symptoms is associated with separation, divorce and widowhood. Longitudinal studies of elderly persons living in the community revealed that hypochondriacal episodes are often transient, lasting a few months to several years. The hypochondriacal reaction is often a maladaptive response to social stress[17]. Another study[18] concludes that hypochondriasis is less a direct function of stressful life events than of the underlying personality, i.e. a characteristic way of perceiving life events. Patients with transient hypochondriacal reactions are common in a general medical clinic. A recent report[19] notes that, among outpatients confronted with a medical illness, those who are sensitive to somatic sensations and those with personality disorders are more likely to develop hypochondriasis.

TREATMENT CONSIDERATIONS

A number of psychotherapeutic approaches, including individual and group therapy[20], have been used in the treatment of hypochondriacal patients. Frequently, individual psychotherapeutic approaches have been based on the treatment methods for depression in those beyond the age of 60 years. This is understandable, because depression is not an unusual feature of hypochondriasis. However, many approaches have certain features in common such as the recognition of the hypochondriac's hostility toward the medical profession and the need to deal effectively with this hostility. Another is avoiding confrontation, specifically the insistence by the therapist that no pathology is present[17,21]. This is of particular importance to the geriatrician, as hypochondriasis is complicated by the existence of physical disabilities and degenerative disease in the majority of elderly persons.

Hospitalization for extensive medical evaluation is to be avoided[13] as the experience often increases the hypochondriac's conviction that a "missed" serious illness is likely and adds to the resistance to psychotherapy. Medications may be useful and often do have a transient placebo effect. Drugs should be selected with considerable care to avoid the complications of side effects and addictive qualities.

Other Neurotic Disorders

Jerome J. Schulte and David Bienenfeld

Wright State University, School of Medicine, OH, USA

REACTION TO SEVERE STRESS, AND ADJUSTMENT DISORDERS

Before World War II it was generally held that psychiatric patients were constitutionally different from "normals". During World War II it was observed that previously asymptomatic individuals experiencing unusual environmental stress sometimes suffered from transient psychiatric difficulties. This observation led to a reclassification of psychiatric disorders to allow for behavioral and emotional symptoms in people who would return to their premorbid state with the removal of the unusual environmental precipitant[1]. DSM-I and ICD-6 classified these transient difficulties as "gross stress reaction" and "adult situational reaction"; DSM-II and ICD-8 classified them as "transient situational disturbances". ICD-9 introduced the categories of "acute reaction to stress" and "adjustment disorder". ICD-10 defines "acute stress reaction", "post-traumatic stress disorder" and "adjustment disorder"; although DSM-III-R recognized only the latter two of these, DSM-IV recognizes all three.

ACUTE STRESS REACTION

Clinical Features

According to ICD-10, acute stress reaction is a transient disturbance, occurring in persons without apparent mental disorder, in response to exceptional physical and/or mental stress and subsiding in hours or days. The diagnosis should not be made for an exacerbation of symptoms of a diagnosable psychiatric disorder already present, except for accentuation of personality traits. Previous history of another psychiatric disorder does not invalidate this diagnosis. An immediate, clear connection between the stressor and the onset of symptoms should be seen.

Symptoms of this disorder show a mixed and changing picture, with no one symptom predominating for long. They appear within minutes of the stress and resolve rapidly when the stressor is removed or, if the stress remains, symptoms decrease after 24–48 h and are minimal after 3 days.

Typical symptoms include an initial state of "daze", constriction of consciousness, narrowing of attention, decreased comprehension of stimuli and disorientation. Withdrawal, agitation or overactivity may follow. Autonomic signs of panic (tachycardia, sweating, flushing) are common. Amnesia for the traumatic present may also be present. In the elderly, organic factors and life stage events can be predisposing factors to acute stress reaction[2]. The multiple bereavements which are not uncommon in late life can be the precipitants for acute stress reaction.

DSM-IV differs somewhat from ICD-10 in its diagnostic classification of acute stress disorder. Unlike ICD-10, which requires that symptoms appear within minutes of the stress and diminish to minimal intensity after 3 days, DSM-IV requires symptoms to last a minimum of 2 days and allows for persistence up to 4 weeks. DSM-IV also includes dissociative symptoms not included under ICD-10: a subjective sense of numbing, detachment or absence of emotional responsiveness; derealization and depersonalization. Another DSM-IV requirement is that the traumatic event is persistently re-experienced in at least one of the following ways: recurrent images, thoughts, dreams, illusions, flashback episodes, or a sense of reliving the experience; or distress on exposure to reminders of the traumatic event. DSM-IV also requires marked avoidance of stimuli that arouse recollections of the trauma[3].

Differential Diagnosis

The differential diagnosis includes post-traumatic stress disorder (PTSD) and adjustment disorder. PTSD (see below) occurs after a latency period of weeks or longer, while the symptoms of acute stress reaction begin immediately after the traumatic event. The repetitive, intrusive imagery characteristic of PTSD is not usually a feature of the ICD-10 diagnosis of acute stress reaction. DSM-IV, however, does include repetitive intrusive imagery among the features of acute stress disorder. If psychotic symptoms follow an extreme stress, acute (brief) psychotic disorder should be considered. Adjustment disorders are less severe, and longer lasting, than acute stress reactions. Events that precipitate adjustment disorders are also less intense than those responsible for acute stress reactions.

Therapy

By definition, the symptoms of acute stress reaction are time-limited and will resolve without specific therapeutic intervention. Treatment may be requested, however, for intolerable tension or insomnia. For tension, short-term use of benzodiazepines with simple metabolic pathways and short half-lives, such as lorazepam or oxazepam, are safest in the elderly. For insomnia, temazepam or the non-benzodiazepine sedative hypnotic zolpiden[4] are justified. Families and patients may be reassured that the acute response does not indicate a psychotic decompensation, and that the prognosis for rapid recovery is favorable. Acutely, and in the aftermath of the traumatic event, it is useful to help the patient gain mastery over the trauma[5] by using a brief treatment model, consisting of fostering abreaction and integration of the event as

quickly as possible, with the expectation that the trauma victim will return to full functioning. Abreaction can be fostered through individual or group psychotherapy[6].

POST-TRAUMATIC STRESS DISORDER

Post-traumatic stress disorder (PTSD) first appeared in DSM-III but was based on older concepts tied to the history of warfare. Da Costa wrote of "irritable heart" following the American Civil War. In World War I the disorder was known as "shell shock". Early twentieth century psychoanalytic theory called it "traumatic neurosis" and in World War II it was known as "traumatic war neurosis" or "combat neurosis". In DSM-I it was renamed "gross stress reaction", a reaction to great stress in a normal personality. During the peace time between World War II and Vietnam, the category was omitted from DSM-II[7]. ICD-9 defined catastrophic stress and combat fatigue as two diagnoses under the category of acute reaction to stress.

DSM-III defined intrusive re-experience of the trauma, together with emotional numbing, as the central features of PTSD. DSM-III-R placed more emphasis on the avoidance of stimuli associated with the trauma and less on numbing. DSM-IV changed the definition of the trauma to an event where a person experienced, witnessed or was confronted with threatened death or serious injury or threat to physical integrity of self or others. Here, the response to the trauma involves intense fear, helplessness or horror. Also, where DSM-III-R required either numbing or avoidance behavior, DSM-IV requires both[3].

ICD-10 criteria more closely resemble those of DSM-III, highlighting the restriction of emotional responsiveness. In ICD-10 the late chronic sequelae of devastating stress, i.e. those manifesting decades after the stressful experience, should be classified under enduring personality change after catastrophic experience[2].

Clinical Features

The ICD-10 diagnosis of PTSD requires evidence of trauma, or a response to a stressful event or situation of exceptionally threatening or catastrophic nature, likely to cause pervasive distress in anyone. The central symptoms are repetitive and intrusive recollections (flashbacks) or re-enactment of the event in memories, daytime imagery or dreams. The onset follows the trauma with a latency period of a few weeks to months (rarely exceeding 6 months). There may also be a sense of "numbness" and emotional blunting, and avoidance of activities and situations reminiscent of trauma.

Anxiety, depression, suicidal ideation and insomnia are also common in many PTSD patients, particularly with advancing age[7]. PTSD is also associated with alcohol and drug abuse, possibly reflecting attempts to cope with PTSD symptoms. Dissociative symptoms, commonly described in younger PTSD victims, become less prevalent with increasing age[8,9].

It remains a subject of debate what factors, if any, predispose individuals to the development of the post-traumatic stress syndrome. Some traumata, particularly the concentration camp experience, are so severe that symptoms are almost universal in survivors. Because retrospective assessment of function before the traumatic event is always colored by the response to the event, correlations are difficult to draw and empirical analyses have been inconclusive[10]. Certain personality traits (e.g. compulsive, asthenic) and a previous history of neurotic illness may possibly lower the threshold for manifestation of the disorder[2].

PTSD can also develop from bereavement. A recent study surveyed surviving spouses 2 months after their spouses' deaths; 10% of those whose spouses died after a chronic illness met criteria for PTSD; 9% of those whose spouses died unexpectedly met PTSD criteria; and 36% of those whose spouses died from "unnatural" causes (suicide or accident) had PTSD[11]. PTSD can also occur when patients have suffered the "trauma" of having a stroke (9.8%)[12] and upon learning that they have breast cancer (3%)[13].

Although PTSD symptoms can persist for many years, with increased frequency of symptoms towards the end of life[14], the typical course is one of fluctuating symptoms[15] in many cases. One study, examining current PTSD symptoms in elderly World War II and Korean War prisoners of war (POWs), suggested that severity of exposure to trauma and lack of post-military social support were moderately predictive of PTSD. In this study, 53% of POWs met criteria for lifetime PTSD, with 29% meeting criteria for current PTSD, but for those POWs most severely traumatized, the lifetime PTSD rates were 83%, with current PTSD at 59%[16].

There are two types of PTSD to which the elderly seem susceptible: delayed-onset PTSD and chronic PTSD. In delayed-onset PTSD, patients may exhibit signs of the disorder decades after the trauma, and in chronic PTSD symptoms have been persistent since the time of the trauma.

Delayed-onset PTSD is a reactivation of an old PTSD, with many years relatively free of symptoms, or the first onset of symptoms years after the trauma. In some elderly World War II veterans, media coverage commemorating the 50th anniversary of the end of the war triggered PTSD symptoms[17]. Commonly, guilt, distorted memory, emotional numbing, estrangement and feelings of detachment, are seen[18]. Patients in this group can present with physical symptoms of cardiovascular, gastrointestinal and musculoskeletal diseases[10]. Generally, the onset of severe symptoms can be linked to a profound recent life event, such as death of a wife, job retirement or loss of physical integrity from illness[18]. Most often, the contemporary precipitant reawakens emotions and perceptions from the original trauma. Holocaust survivors and prisoners of war have been noted to begin displaying symptoms of PTSD after admission to nursing homes, where they re-experience a loss of freedom and autonomy. World War II veterans found the loss of physical integrity due to somatic illness particularly upsetting, since it evoked memories of a traumatic period when their physical integrity was in jeopardy[9].

Differential Diagnosis

Although adjustment disorders also occur in response to life events, these events are in the normal range of human experience, unlike the extraordinary traumata responsible for PTSD. Specific features of numbing and flashbacks do not occur, and adjustment disorders, by definition, do not last more than 6 months. Acute stress reaction is characterized by a more variable clinical picture that resolves within days.

While anxiety and depression are common features of PTSD, generalized anxiety disorder and phobic disorder have anxiety as a more specific and central symptom. Major depression is marked by deep and persistent mood disturbance, usually with loss of reactivity; dysthymia results in chronic, indolent dysphoria. None of these disorders includes the specific symptom of intrusive recollections.

Therapy

The signs and symptoms of post-traumatic stress disorder include distorted expectations and perceptions, mood disturbances, psychophysiological symptoms and social withdrawal. Thus,

common sense dictates, and empirical data confirm, that multimodal treatment is most advisable. Psychosocial intervention and pharmacotherapy each has its place. At all ages, the psychotherapy of PTSD starts with the retelling of the story of the events before, during and after the traumatic episode. The goal is to integrate the experience with the person's life history; the method is to frame the events from the perspective of the intact self, rather than leave them relegated to the weakened self of the past. It is particularly important in older patients, given the chronological distance from the event, to differentiate objective properties of the trauma from the fantasy attributions it accumulates over time[19].

Group therapy has been found to be particularly useful. Matching patients by age and by setting of trauma enhances feelings of understanding and group identification[20]. The focus of the group is on recurring memories, and benefits patients by relieving long-held guilt through objective evaluation of the traumatic incident, as well as enhancing their ability to tolerate life stressors[18,21,22].

Antidepressants can offer symptomatic relief by diminishing dysphoria, intrusive thoughts, insomnia and nightmares. In particular, selective serotonin reuptake inhibitors (SSRIs) can be effective, especially in reducing avoidant symptoms[24,25]. β-Adrenergic blocking agents have been used in younger PTSD patients for relief of symptoms of autonomic arousal, tremors and startle reactions[26]. Older patients, however, are less likely to display a clinical profile of hyperarousal, and are more susceptible to the cardiovascular complications and organic mood disorders associated with adrenergic blockade. Benzodiazepines should be avoided as much as possible, since they can cause paradoxical excitation and frequently induce subtle cognitive impairment in aging individuals[27].

ADJUSTMENT DISORDER

The diagnosis of adjustment disorder refers to a state of subjective distress or emotional disturbance, interfering with social functioning or performance, arising in a period of adaptation to a significant life change or subsequent to a stressful life event. It is assumed that the condition would not have arisen without the stressor. In ICD-10, onset is usually within 1 month of the stressor; in DSM-IV, it can be within 3 months of the stressor. In both ICD-10 and DSM-IV, duration of symptoms does not exceed 6 months, except in the case where the stressor is chronic (e.g. a chronic general medical condition) or the stressor has enduring consequences (e.g. the financial and emotional difficulties resulting from a divorce)[3].

Clinical Features

Symptoms of adjustment disorder may include: depressed mood, anxiety, worry, impairment in performance of daily routines and inability to cope or plan ahead. Adjustment disorders can be specified as brief depressive reaction, prolonged depressive reaction, adjustment disorder with predominant disturbance of other emotions, adjustment disorder with predominant disturbance of conduct, or adjustment disorder with mixed disturbance of emotions and conduct.

The precipitating events for adjustment disorders can affect social network or values, and may involve the individual, his group or community. Common events causing such symptoms in older patients include physical illness or injury, placement in a nursing home and retirement. The events, while subjectively profoundly meaningful, are of considerably smaller magnitude than those precipitating acute stress reaction and PTSD. Individual predisposition and vulnerability to these stressful life events thus plays a greater role in the occurrence of adjustment disorders. Poor pre-stressor social and coexisting physical problems[28], current dementia[29] and a history of a past psychiatric disorder[30] all increase vulnerability to adjustment disorders.

Therapy

The cornerstone of treatment for adjustment disorders is focal psychotherapy. Based on a psychodynamic understanding of emotions and behavior, focal therapy identifies the most specific nidus of current distress and views it in the context of the patient's core conflicts or deficits. The therapy is of relatively brief duration, usually 6–20 sessions. The major techniques employed are clarification and confrontation[31].

Quite frequently, the precipitating event can be framed as a narcissistic threat or injury. In psychotherapy, the patient will come to view the therapist as a self-object, looking for restoration of the self-esteem provided by the lost function, role or friend. The therapist helps restore the wholeness of self by allowing the patient to modify his/her expectations of him/herself and environment[32].

DISSOCIATIVE AND CONVERSION DISORDERS

In the last three decades of the nineteenth century, dissociation was studied extensively by Janet and conversion by Freud. DSM-I incorporated the concepts of dissociation and conversion into its classification scheme. Conversion reaction was assigned to hysterical neurosis, and amnesia was placed in the category of dissociative reaction. In DSM-II they were united under the heading of hysterical neurosis, but divided into conversion type and dissociative type. In DSM-III, DSM-III-R and DSM-IV the two conditions were renamed and separated once again. Hysteria, conversion type, became conversion disorder and was assigned to somatoform disorders. Hysteria, dissociative type, was expanded into the dissociative disorders[33]. ICD-10, however, continues to contain both under the heading of dissociative disorders.

DISSOCIATIVE AMNESIA

Dissociative amnesia is characterized by loss of memory, usually of important recent events, that is too great to be explained by ordinary forgetfulness or fatigue; and amnesia, either partial or complete, for recent events that are of a traumatic or stressful nature. The amnesia is usually partial and selective. The extent and completeness of the amnesia varies from day to day and between inquirers, but a persistent common core cannot be recalled in the waking state. Complete, generalized amnesia is rare and is usually part of a dissociative fugue. Affective states in amnesia are varied but severe depression is rare. Perplexity, distress and varying degrees of attention-seeking behavior may be evident, but calm acceptance is also sometimes striking. Purposeless local wandering may occur, but is rarely accompanied by self-neglect and rarely lasts more than a day or two. Often in dissociative amnesia, new learning is preserved[34]. Disturbing external circumstances causing despair or anxiety may predispose an individual, but a single event is usually at the center of the syndrome.

Dissociative amnesia is uncommonly reported in the elderly, but has been seen in World War I combat soldiers[35] and soldiers in other conflicts. In most patients the amnesia is short-lived, 75% of cases lasting between 24 h and 5 days[36]. Its features resemble those of more frequently observed disorders. Organic amnesia is usually anterograde[34]. In postconcussional syndromes there may

be a combination of hysterical and organic amnesia that can be difficult to untangle. In dementia, memory loss is seen in the context of global cognitive impairment, which is stable over a period of weeks to months. The syndrome of pseudodementia also features variable memory impairment, but affective disturbance, usually severe depression, is evident[37].

DISSOCIATIVE FUGUE

Fugue exhibits all the features of dissociative amnesia, plus an apparently purposeful journey away from home or place of work during which self-care is maintained. A new identity is assumed and organized travel may be undertaken to places previously known and of possible emotional significance. Although there is retrograde amnesia during the fugue, behavior during fugue is normal.

A severe precipitating stress is almost universal as a precipitant of dissociative fugue. Times of marital discord, financial difficulty, major role change or personal loss may precede the fugue. Depressed mood is frequently present before fugue symptoms are displayed[34].

Fugue is rare in elderly people. Because its features, with the exception of travel, are identical to those of dissociative amnesia, it has been proposed that the two disorders be considered as one.

Treatment

Therapy for dissociative amnesia and dissociative fugue is virtually identical. Patients usually seek treatment after the amnestic period has ended. They desire help in recovering memory of events during the fugue. Hypnosis and short-acting barbiturates have been used to reconstitute repressed memories, although typically they return spontaneously. Psychodynamic psychotherapy has been used to facilitate resolution of conflicts that lead to fugue states. This treatment may decrease the vulnerability of the patient to dissociate in future times of stress[38].

DISSOCIATIVE DISORDERS OF MOVEMENT AND SENSATION (CONVERSION DISORDERS)

In conversion disorder, there is a loss or alteration in movements or sensations (usually cutaneous) in a patient presenting as having a physical disorder. No somatic condition can be found, however, that explains the symptoms. Instead, the symptoms represent the patient's concept of the physical disorder, which may be at variance with physiological or anatomical principles. Here, mental state and social situation suggest that disability resulting from the loss of function is helping the patient to escape an unpleasant conflict, or helps the patient to express dependency or resentment indirectly. Conflicts may be evident to others, but the patient often denies their presence and attributes distress to the physical symptoms or the resulting disability.

In making the diagnosis it is essential that: (a) evidence of a physical disorder is absent; and (b) sufficient knowledge of the psychological and social setting and personal relationships of the patient allows a convincing formulation of the reasons for the disorder.

Predisposing factors to conversion disorder are premorbid abnormalities of personal relationships and personality. Also, close relatives or friends may have suffered from physical illness with symptoms resembling the patient's. A few patients establish a repetitive pattern of reaction to stress by production of these disorders, which can continue into middle and old age[2].

The most important differential diagnosis is the group of somatoform disorders (although DSM-IV classifies conversion disorder as a somatoform disorder instead of a dissociative disorder). In the latter, the patient's presentation centers around persistent requests for medical attention and pervasive concern with the perceived medical disorder; patients with conversion disorder are much more likely to take their presumed illnesses in stride. Conversion disorders generally begin in adolescence and young adulthood, and occur in single or recurrent episodes with substantial remission. Somatoform disorders may not increase in prevalence with increasing age, but they tend to assume the quality of a pervasive character style with little remission.

Most conversion disorders remit with non-specific, supportive interventions. Hypnosis, anxiolytics and behavioral relaxation exercises may be helpful. Also, psychotherapy aimed at helping the patient recognize and cope with the psychosocial stress that provoked the symptom can be impressively beneficial if the patient can be engaged in a cooperative alliance of therapeutic curiosity.

The prognosis of conversion disorder is generally good, since conversion symptoms are of short duration with abrupt onset and resolution. A few become chronic, and some recur, most commonly when the precipitating stress is chronic or recurrent, when there is other psychopathology or when there is marked secondary gain.

NEURASTHENIA (FATIGUE SYNDROME)

Historical Perspective

George Beard introduced the term 'neurasthenia' in 1869. He viewed neurasthenia as a physical illness due to loss of nerve strength. Janet differentiated psychasthenia from neurasthenia. Freud similarly separated anxiety neurosis, a "psychoneurosis", from neurasthenia, an "actual neurosis" he attributed to misdirected libidinal energy.

In World War I, the syndrome was defined by the term "shell-shock"; in World War II, "operational fatigue". Although it remains in ICD-10, the diagnosis of neurasthenia was deleted from DSM-III and replaced by dysthymia. In the USA the symptom cluster known as chronic fatigue syndrome is almost identical to the current ICD classification of neurasthenia[39–41].

Clinical Features

Neurasthenia is characterized by persistent, distressing complaints of fatigue after mental effort, or complaints of bodily weakness and exhaustion after minimal physical effort, along with at least two of the following: muscular aches and pains, dizziness, tension headaches, sleep disturbance, inability to relax, irritability or dyspepsia. If autonomic or depressive symptoms are present, they cannot be sufficiently persistent and severe to fulfill the criteria for any more specific disorder[2].

Differential Diagnosis

Differential diagnosis includes primarily major depression and somatoform disorders. In the elderly it is especially important to rule out depression, since somatic complaints and fatigue are common presentations of depressive disorders in late life. Physical symptoms with no demonstrable organic pathology are the essential features of somatoform disorders. However, these complaints do not include the specific physical symptoms of fatigue or exhaustion found in neurasthenia.

Therapy

Specific treatment for neurasthenia has not been established. Given the high likelihood, particularly in old age, that the neurasthenic picture is a manifestation of a mood disorder, treatment with antidepressant medication and psychotherapy, as for depressive conditions, is generally warranted.

Personality Disorders: Aetiology and Genetics

Victor Molinari[1], Tom Siebert[2] and Marvin Swartz[2]
[1]*VAMC Psychology Service, Houston, TX, USA,* [2]*Duke University Medical Center, Durham, NC, USA*

According to DSM-IV[1], "A Personality Disorder is an enduring pattern of inner experience and behavior that deviates markedly from the expectations of the individual's culture, is pervasive and inflexible, has an onset in adolescence or early adulthood, is stable over time, and leads to distress or impairment" (p. 629). Since the first edition of this chapter was published, there has been an ever-expanding body of knowledge about personality disorder (PD) in older adults. Notably, there has even been the publication of the first book[2] solely devoted to PD in older adults. However, as we shall see, there remain many unanswered questions spawned by thorny conceptual and methodological quandaries in this controversial area.

PD in older adults is an important area of study for a number of reasons. First, since PD affects the way an older adult copes with life, individuals with specific PDs may be less able to successfully negotiate age-related losses (e.g. obsessive–compulsive, dependent) or the interpersonal compromises necessary for peaceful institutional living (e.g. borderline, narcissistic). Second, PD can influence the presentation of Axis I symptomatology, frequently generating complicated assessment dilemmas. For example, disruptive behavior in the nursing home may camouflage the fact that the person is suffering from a depression that is exacerbating premorbid antisocial personality features. Third, just as for young adults, the presence of PD should modify treatment strategies and prognosis of co-morbid Axis I disorders in certain geriatric settings.

This chapter will summarize what is known about the etiology, genetics, epidemiology, assessment, prognosis and research implications of PD in older adults.

AETIOLOGY AND GENETICS

Reviewing PD necessitates some understanding of the complexity of the terms "personality disorder" and "personality", as well as their classification. Personality can be conceived as two interactive elements, representing "nature" and "nurture": temperament, a reflection of a genetically determined, constitutional disposition; and character, made up of learned attributes, which begin coalescing in early childhood, reflecting culture, norms and upbringing. Studies have focused on each of these elements in order to clarify the etiology of personality and PD, but these investigative efforts have been rendered more complicated by different measurement approaches.

Concerning PD among the elderly, it is helpful to focus on dimensional aspects of personality as well as the categorical diagnosis of PD. Because of the numerous biological changes that occur with aging, a major question for the geriatric clinician concerns the stability of personality traits throughout the aging process.

Most researchers agree that there is no uniform, stereotypic change in personality traits in late life. Cross-sectional and longitudinal investigations of personality across the life cycle[3] report the general stability of individuals' major traits. However, it is also clear that certain adults do change for the better or worse[4], perhaps due to some of the unique challenges they face over the lifespan.

Late-life theorists have made important contributions to conceptualizing those challenges that promote personality development. Erikson's[5] crisis of "integrity vs. despair" marks the culmination of his psychosocial framework. The challenge of this final stage is the individual's acceptance of the integrity of his/her self; failure results in a fear of death and an inability to find meaning in the life cycle. Erikson felt that the successful resolution of this stage depends on an adequate resolution of previous crises. From the point of view of personality, failure here may also trigger global dissatisfaction and lowered self-esteem. Erikson's developmental stages, intended for a practitioner audience, were not rigorously defined and were based on clinical and theoretical considerations rather than research data.

Levinson *et al.*'s[6] developmental scheme is based on their research on the life cycle. They view development as a series of eras and cross-era transitions. Older adults are seen from the point of view of the late adult transition and late adulthood. The late adult transition (age 60–65) is marked by major changes in role structure, physiology and intrapsychic challenges. It is possible that adaptation to these challenges provokes changes in personality structure (i.e. a decrease in authoritarianism; locus of satisfaction shifting from the self to others). Haan and Day[7] traced the relative prominence of different personal dimensions (such as information processing, inter-personal reaction, manner of self-presentation and responses to socialization) throughout the life cycle from adolescence onwards. Although most dimensions were stable, some changed in an orderly manner with age. Still others changed in a stage-wise manner. The authors believed that their results fitted an Eriksonian developmental model with an essential "sameness" of major personality functions, punctuated by times of regress before progress and longer periods of orderly change.

The investigation of constitutional factors that contribute to PD is affected by a number of methodological difficulties. Few studies have looked specifically at DSM Axis II criteria; many have looked at other variables, such as neuroticism and sociability, which cannot be compared well with PD as defined by DSM.

The most intensive studies of familial factors have been conducted on those with antisocial PD. Crowe[8] summarized data from twin studies in strong support of a heritable component

for antisocial PD. The mean concordance rate for monozygotic twins for the disorder was double that of dizygotic twins (68% vs. 33%). Adoption studies[9,10] have also found "temperamental" factors to be a major determinant for antisocial PD. Family studies find increased rates of substance abuse, antisocial PD and other psychopathology in first-degree relatives of felons, many with the diagnosis of antisocial PD[11].

Schizotypal PD has been well examined from a genetic perspective and owes much of its appearance as a diagnosis to that association. Schizotypal PD has a significant heritable relationship to schizophrenia. Kendler *et al.*[12] were unable to find an equivalent environmental association. Torgersen[13] confirmed the genetic link between schizoid and paranoid features of schizophrenia and schizotypal PD.

The final disorder that has yielded studies on heritability is borderline PD. A credible familial association has been found between borderline PD, affective disorders and other PD[14]. Previous associations between "borderline states" and the schizophrenic spectrum have been difficult to interpret because of differing definitions of "borderline states" and the relationships of these definitions to current DSM-IV criteria for borderline PD. Individuals with a history of impulsive or affective instability, which more closely fit present borderline PD criteria, may not have a greater prevalence of schizophrenia in their relatives[14].

In summary, there is clear evidence of heritability for some PD but much that remains unexamined. As Clarkin, Speilman and Klausner[15] note in their conceptual overview of PD in the elderly, the research on the relationship of genetic factors to PD is sparse, and speculations concerning the neurobiology of PD remains premature. The remaining "nurture" factors also comprise a significant component, but have yet to be clarified.

Neurobiological studies have been very rare. EEG slow-wave activity has been associated with antisocial PD. Borderline patients have a significantly higher percentage of marginal EEG abnormalities than controls[16]. They also show changes in cerebrospinal 5-hydroxyindole-acetic acid (5-HIAA), a measure of serotonin activity that is correlated negatively with measures of aggressivity. Finally, schizotypal and borderline PD have been linked with low platelet monoamine oxidase (MAO) activity[17,18]. Individuals with schizotypal PD may also show impaired smooth pursuit eye movement.[19,20].

ASSESSMENT

Assessment of PD requires an examination of variables that may be difficult to measure, especially in older adults. There are, for instance, problems in obtaining a reliable diagnosis. Since all the standardized instruments used to measure PD have been developed for a younger population, these devices thereby require more administration time for older adults (since they have longer personal histories). Consequently, there is no "gold standard" of diagnosis for PD in older adults. Molinari *et al.*[21] studied geropsychiatric inpatients with depression, and found general discordance between patient self-report, family informant ratings, social worker evaluations, and consensus case conference categorical diagnosis of PD. It appears that there are varied perceptions of an individual's personality, all of which should be taken into account for a comprehensive evaluation of Axis II pathology.

From a clinical perspective, PD is quite common in medical practice, yet infrequently recognized. Mental health professionals are loathe to diagnose PD, particularly in old age, due to concerns over pejorative bias, pessimistic belief in Axis II changes, managed care reimbursement biases, and focus on medical or Axis I pathology (particularly cognitive impairment) in old age. Often the PD patient presents with unrealistic expectations, complaints and demands, and an inappropriate interpersonal stance. Essential features of PD, regardless of age, will include: maladaptive behavior as a lifestyle; inflexibility in managing interpersonal situations; multiple physical, social and interpersonal problems; and externalization of these problems in the absence of psychosis[22]. Yet these same features are sometimes accepted, erroneously, as part of the aging process. In a geriatric setting, somatic presentations of PD are common, which can complicate "teasing out" true co-morbid medical/cognitive problems from personality dysfunction. Patients with PD frequently present with chief complaints of "bad nerves", sleeplessness, non-specific requests for help and pain syndromes. In addition, Axis I disorders can confound appropriate diagnosis and confuse the long-term picture. For example, evidence suggests that older depressives are significantly more likely to have lifetime personality dysfunction than controls[23,24]. Therefore, it behooves the clinician to ascertain whether a pattern of historically maladaptive personality traits exist in the older patient with depression. Treatment of the depression may very well result in a symptom picture reflecting a baseline PD, rather than a depression in partial remission.

EPIDEMIOLOGY

Some early anecdotal reports suggested that personality characteristics become uniformly less harsh with age[25,26]. Other clinicians working with older adults believed that the "high-energy" PDs (e.g. Cluster B) mellow, while the "low-energy" PDs (e.g. Cluster C) may be aggravated by the aging process[27–29]. DSM-IV[1] states that, "Some PDs tend to become less obvious or remit with age, whereas this appears to be less true for some other types" (p. 632). This statement underscores some of the more recent empirical work in this area, and contrasts with the more benign general appraisals of DSM-III[30] and DSM-III-R[31], which merely note that PD becomes "less obvious" with age. Early research yielded wide variability in PD prevalence rates due to inadequate definitions of PD, non-standardized measures, and different samples of older adults. With the introduction of DSM-III and the development of instruments tied to DSM-III criteria, some consistent findings have emerged. This section on epidemiology will therefore largely focus on studies using standardized measures, and will be divided into community, institutional, outpatient and depression studies.

Community Settings

In community settings, two studies[26,32] compared young and older adults utilizing the Coolidge Axis II Inventory. Coolidge *et al.*[26], found a greater need for organization and more restricted affect in older adults, while Segal *et al.*[32] found that older adults were significantly higher on obsessive–compulsive and schizoid PD, but lower on the antisocial, borderline, histrionic, narcissistic and paranoid scales. Ames and Molinari[33] used the Structured Interview for Disorders of Personality scale (SIDP-R) and detected a trend of less PD in older adults, with significantly fewer older adults meeting the criteria for more than one PD. Cohen *et al.*[34] used the Structured Psychiatric Examination and found that those over the age of 55 were less likely (6.6% vs. 10.5%) to have PD, due to a three-fold decrease of Cluster B PD in older adults. These data documenting personality "mellowing" in older adult community samples are in stark contrast to the results of a more recent study by Segal *et al.*[35], who found that a high number (63%) of very old ($X = 76.2$ years) community-dwelling adults met PD criteria by self-report. However, this study was potentially flawed by failure to take into account the cognitive

and sensory status of this aged sample, many of whom may have misunderstood the questions or exhibited executive deficit-related personality alterations.

Institutional Settings

Early PD prevalence rates in nursing home settings were reported to be 12–15%[36,37], while for geropsychiatric inpatients, PD estimates were more variable (7–55%). In a large sample of hospitalized male veterans, Molinari *et al.*[38] conducted a cross-sectional investigation of personality changes across different age groups for those clinically diagnosed with PD. Older adults with PD were more responsible and less impulsive, paranoid, energetic and antisocial than young adults diagnosed with PD. Kunik *et al.*[39] studied 547 older psychiatric inpatients, and found that a consensus case conference diagnosis of PD varied widely, depending upon the specific co-morbid Axis I diagnosis (e.g. 6% for patients with an organic mental disorder, but 24% for those with depression). Only two studies of geropsychiatric institutionalized patients utilized standardized instruments. Molinari *et al.*[40] used the SIDP-R and found that older adults had PD rates similar to those of a young adult comparison sample; however, older adults were less likely to meet criteria for more than one PD, and clinical diagnoses yielded fewer PDs than the SIDP-R. Likewise, Coolidge *et al.*[41] used the Coolidge Axis II Inventory and found similarly high PD rates among young (66%) and old (58%) chronically mentally ill patients, but the younger group was more likely to be specifically diagnosed with antisocial, borderline, and schizotypal PD.

Outpatient Settings

The findings from the lone study conducted with a structured PD scale in a geropsychiatric outpatient setting are consistent with the latter inpatient studies. Molinari and Marmion[42] found that older adults were less likely to meet the criteria for more than one PD than younger adults, and clinical diagnosis again yielded fewer PDs than the SIDP-R.

Depression

One area of intense study has been the relationship between PD and depression in older adults. Kunik *et al.*[24] studied 154 depressed older inpatients and identified 24% with co-morbid PD, while Molinari and Marmion[43] determined that 63% of depressed geropsychiatric outpatients met PD criteria. Thompson *et al.*[44] found that 33% of depressed older adults who were being treated with psychotherapy in a geropsychiatric outpatient clinic met DSM-III PD criteria. In a study investigating the relationship between PD and functioning in acutely depressed older psychiatric patients, Axis II pathology was found to be associated with greater disability and more impaired social and interpersonal functioning[45]. In their review of the literature on PD in older adults, Agronin and Maletta[46] posit that PD in late life may be intrinsically related to Axis I pathology, particularly major depressive disorder.

Summary of Epidemiological Studies

In an attempt to lend clarity to the burgeoning literature on PD in older adults, Abrams and Horowitz[47] conducted a meta-analysis of the most methodologically sophisticated epidemiological studies. They inferred a PD prevalence rate of 10% (with a range of 6–33%) for those over the age of 50, and concluded that, "at this time the literature neither supports nor contradicts previous suggestions of an age effect". However, these authors remark that the bulk of the evidence supports, at least for certain PDs, a decline in frequency and intensity with age. The cause for this decline is one of the most controversial and debated topics in the literature on PD in older adults. Four main reasons have been postulated.

First, there is a general mellowing of the "high-energy" Cluster B PDs due to biological (reduced testosterone in males) and developmental changes (those with PD finally master a single interpersonal strategy to manage stresses). This accounts for the consistent result that older adults are less likely to meet the criteria for more than one PD, and is also supported by the recent study of Segal *et al.*[32], who discovered lower levels of dysfunctional coping styles in older adults.

Second, the decline in "high-energy" PD relates to the greater mortality rates of those with Cluster B PD in their younger years. Older adults with PD are thereby a selective sample of less extreme PD "survivors". Third, PD is generally underdiagnosed, particularly in older adults, where cognitive and medical causes are emphasized or personality disturbance (avoidance, dependency, lability) is viewed as normal[48].

Fourth, the decline in PD with age is a methodological artifact, since some DSM criteria are age-insensitive. For example, occupational and vocational impairment are often irrelevant to older adults. From this point of view, there really is no true decline in PD rates with age, just a change in form that is inadequately assessed. These so-called "geriatric variants"[49] reflect the more subclinical, non-specific or age-relevant PD traits that account for PD NOS (not otherwise specified) to be diagnosed with particular high frequency in older adults. The construction of a new geriatric nosology has been proposed to accommodate the late life changes in Axis II pathology[46,47,49]. Such re-classification will need to: (a) reconsider the diagnostic requirement that maladaptive PD behavior be rooted so early in young adulthood; (b) routinely address Axis II pathology in the context of more acute Axis I symptomatology; and (c) integrate age-related developmental, medical (Axis III) and psychosocial/environmental stressors (Axis IV) with Axis II manifestations[46].

PROGNOSIS

Unfortunately, only a few seemingly contradictory studies have investigated the prognosis of PD in late life. In two separate studies of geropsychiatric outpatients, PD was found to be a poor prognostic sign for the psychotherapeutic treatment of depression[44,50]. However, Molinari[51] examined the 1 year relapse rates for 100 male geropsychiatric inpatients and found no significant differences for those diagnosed with and without PD. Consistent with Kunik *et al.*'s[24] finding that PD diagnosis had no impact on the acute response of inpatient treatment for depression with older adults, no differences were found in relapse rates for a subgroup of depressed inpatients with and without PD[51]. It appears that in inpatient geropsychiatric settings, Axis I symptomatology overrides Axis II pathology as an outcome predictor, probably related to the complex combination of medical, cognitive and psychiatric symptoms often observed in those older patients needing acute care.

RESEARCH IMPLICATIONS

Base rates mandating prohibitively large sample sizes render it difficult to make valid statements concerning age-related changes for most individual PDs. To expand our current inadequate

knowledge base, research should concentrate on PD clusters and PD with older adults must be conducted using reliable scales tied to DSM-IV criteria across varied settings (e.g. medical, nursing home, psychiatric inpatient, psychiatric outpatient) populations (e.g. old-old, females, multicultural) and methodologies (e.g. longitudinal, cross-sectional). The inclusion of age-graded criteria for Axis II and perhaps also Axis I should be investigated. At the very least, since all the PD scales currently in use have been developed for younger adults and have yielded generally modest reliability ratings for most PD categories, validity studies must be conducted specifically with older adults[48]. Such studies must take into account the effect of cognitive status and medical problems on the responses of older adults. In this way, research concerning the psychological/developmental history of individuals with PD will generate valuable prognostic and treatment data. Research should also explore those PD features underlying late onset Axis I disorders. Hopefully, more sophisticated methodologies will probe the relative and combined merits of pharmacotherapy and different types/modes of psychotherapy (e.g. cognitive–behavioral vs. interpersonal; group vs. individual). Heuristic models of the interrelationship between the underlying neuropsychiatric and biological substrate of temperament, genetic factors and psychosocial changes in personality with aging must be generated. Finally, the ethical and clinical issues involved in the management of "difficult personality-disordered" patients in hospital, rehabilitation and nursing home sites should be explored, so that the needs of individuals can be balanced with those of families, staff and patient/resident peers[52–54].

SUMMARY

Over the last decade, there has been an increasing amount of research on PD in older adults using structured scales tied to DSM criteria. Major findings are:

1. Although still common in older adults, Cluster B pathology is less prevalent than in the young adult population; Cluster C pathology may be relatively more prominent in older adults.
2. Older adults are less likely to receive more than one PD diagnosis, suggesting that they may finally develop one main coping strategy to fulfill their interpersonal needs.
3. There may be an age-related mellowing of the "high-energy" personality characteristic of individuals with PD, and/or there are "geriatric variants" of PD not tapped by DSM.
4. There is a positive association between depression and PD diagnosis.
5. PD in older adults is prognostically useful in outpatient settings, where the Axis I symptomatology is less severe.
6. There are poor concordance rates of PD diagnosis between clinical examination, structured interviews and self-reports, suggesting the need for data collection from a variety of sources.

Although age-related changes in PD expression are probably in the less volatile and impulsive direction, novel PD manifestations can still create a significant burden in stressful caregiving contexts for family members, friends, healthcare professionals and administrators of institutions attempting to support a flawed but vulnerable older adult. Future research guided by conceptual advances promises to yield exciting progress in assessment and treatment.

Theoretical and Management Issues

Robert C. Abrams
The New York Hospital–Cornell Medical Center, New York, USA

The elaboration by DSM-III[1] of a domain of pathological personality typologies into the well-known Axis II personality disorders has stimulated an outpouring of clinical research. While most of this research has reaffirmed the usefulness of the personality disorder concept, substantial theoretical and methodological problems persist. For example, there is considerable heterogeneity of symptoms within individual disorders and overlap among different disorders[2]. It can be argued that the Axis II personality disorders to some degree lack both convergent and discriminant properties. Moreover, the theoretical underpinning of personality disorders is far from clear. Are these entities derived from interactions of heritable traits, as suggested by Cloningen[3], or are they based on a pathological intrapsychic organization, as suggested by Kernberg[4]? Alternatively, are personality disorders better understood in interpersonal or learning-behavior contexts? It has proved possible to apply each of these theoretical models; personality disorders are, by definition, relatively enduring patterns of dysfunctional behavior that permeate the entire person, are not due to a single abnormality and lead to pain and suffering of people in the patient's world, sometimes more than in the patient him/herself. It is thus not surprising that a variety of explanatory models have been used in efforts to understand these disorders.

Very little attention, however, has been directed to the existence of personality disorders in the elderly and their clinical management, despite the considerable interest in long-term follow-up studies of borderline personality disorder patients[5,6]. In part, this neglect may reflect the original perspective of DSM-III and DSM-III-R[7], that personality disorders are largely attenuated by middle- and old age. Probably another reason is the ongoing uncertainty about how best to assess personality in the elderly. Aging imposes complexities on the already difficult study of personality, adding the confounding factors of brain changes, environment and time. Finally, concepts of normal and pathological adult personality functioning may not be relevant to old age.

In this chapter the topic of personality disorders in old age will be approached first with a discussion of age-related personality change, followed by a review of methodological and clinical issues, including comments on the assessment of DSM personality disorder criteria in the elderly. It will conclude with a discussion of treatment and management.

THE AGING PERSONALITY: DO PEOPLE ACTUALLY CHANGE?

Although the aging personality has been the subject of extensive speculation[8–10], there has been no closure on the question of whether, or in what ways, people change in their dealings with the world; it is still not known whether change or persistence predominates over time. The literature in this area to date can be divided along theoretical and methodological lines into dimensional, categorical and psychoanalytic–developmental models, each with a different set of assumptions.

Using mostly dimensional approaches, conceived as continua of stable traits along which all individuals lie, the psychological literature suggests a picture of progressive changes in motivations and values over the adult years. For example, there appear to be steady increases from early to middle adulthood in self-confidence, independence, humanitarian concerns and personal rigidity[8–9]. Large-scale investigations of medical patients and normal subjects have been carried out using the Minnesota Multiphasic Personality Inventory (MMPI)[11,12]; older adult medical patients tended to score higher on scales measuring introversion, concern with health, immaturity and depression than younger adult medical patients. A decline in criminality with advancing age has also been well documented[13]. Together, these data suggest that traits related to a quiet, inner-directed attitude most typify the aging personality. The MMPI data in particular seem to lend support to the concept of disengagement, or gradual withdrawal from productive activity, as the pre-eminent social-psychological model for age-related personality changes[14]. The reduction in sociopathy and attenuation of hostile aggressive traits have also been highly consistent MMPI findings[1,12].

However, such dimensionally-modeled studies have not pointed conclusively to the existence or direction of age-related personality changes. For example, the MMPI data referred to above are based on large-scale cross-sectional studies involving thousands of medical patients and normal adult subjects, but have not been confirmed in longitudinal studies; the longitudinal MMPI studies have instead emphasized the stability of personality profiles of the individuals over time[15,16]. Similarly, dimensional scores on the Eysenck Personality Inventory Psychoticism (P), Extraversion (E) and Neuroticism (N) subscales show substantial persistence over 30 year periods[7].

Categorical models, such as the DSM-IV Axis II personality disorders, are operationally defined typologies of personality psychopathology, or clinical phenotypes. These models have been relatively little used to examine the aging personality. At the present time, for example, there is scarce cross-sectional information on DSM-IV personality disorders in the older age groups and virtually no longitudinal studies of personality disorder patients that track outcome as far as senescence. However, based upon cross-sectional regression analysis of the relationships of different personality disorder traits with age, Tyrer[18] has suggested that personality disorders can be divided into mature and immature

categories. The mature disorders include obsessive–compulsive, schizotypal, schizoid and paranoid; these personality disorders show more stability and less variation with age than others. Schizotypal personality disorder, for example, would be expected to behave more like schizophrenia from the longitudinal perspective because of its spectrum and genetic relationships to the Axis I disorder[5–8]. The immature or flamboyant personality disorders include the borderline, antisocial, narcissistic, histrionic and passive–aggressive categories; these personality disorders may be more evident in younger individuals and may have earlier onset than mature personality disorders. In this scheme, mature personality disorders consist primarily of the Cluster A (odd–eccentric) disorders plus obsessive–compulsive disorder from Cluster C (anxious–fearful); immature personality disorders consist primarily of Cluster B (dramatic–emotional) disorders, plus passive–aggressive disorder from Cluster C.

Other authors, notably McGlashan[5] and Stone[6], have commented, on the basis of follow-up data, that the florid borderline symptomatology seen at index admissions substantially declines by the second decade of follow-up. Both male and female patients appear to advance occupationally and globally, as well as symptomatically, with time[5]. Tyrer[18] also reviewed data suggesting that patients with personality disorders have higher mortality by suicide than other psychiatric patients for a period of 5 years from diagnosis, after which differences in suicide rates between personality disorders and other psychiatric patients become negligible. These mortality data have been interpreted by Tyrer to support a maturation hypothesis, especially for antisocial and other immature personality disorders, in which impulsiveness and suicide become less likely over time. There are also suggestions that mature personality disorders are more frequent in the geriatric population than immature disorders[19,20].

Thus, it is possible to speculate about a "flattening" over time of at least some specific types of personality disorder symptomatology, which might explain why geriatric patients seem to have diffuse Axis II symptomatology, with relatively fewer full diagnoses of personality disorder[19,20]. In the case of borderline personality disorder, the assumption that symptoms are enduring and inflexible has been challenged; this disorder might now be viewed as a state of delayed maturation that improves with time, rather than as a set of chronic defects. However, even in borderline personality disorder, the improvement may not be uniform across different spheres of functioning. McGlashan[5] has suggested that borderline patients may improve considerably in occupational or instrumental functioning, yet never develop satisfactory personal relationships.

Moreover, aging does not necessarily imply linear reduction in severity of the immature personality disorders. An epidemiological study of personality disorders conducted by Reich *et al.*[21] found the dramatic cluster to be described by a reverse J-shaped curve, in which core traits decline to age 60, then take a slight upturn. Geriatric clinical experience also suggests that there are some individuals who have relatively mild personality dysfunction in young and middle adulthood, but in old age develop a marked and persistent worsening of these trends[22]. Thus, late-onset or emergent personality disorders are possible. Alternatively, individuals with lifelong personality dysfunction can have an affective denouement; they may be more likely to develop depression in old age, as some data suggest[19,20].

A recent body of contributions from psychoanalytic theorists and clinicians has been leading to a developmental theory of the second half of life[23]. Freud's early ideas about the declining plasticity of the personality[24], based on experience in clinical psychoanalysis, have given way to the notion that psychosocial development is continuous throughout life. Successful disengagement from active working and parental roles, and acceptance of the inevitability of death, are several of the proposed developmental tasks of aging. For example, awareness of one's eventual death has been thought to be marked by universal apprehension and, in some individuals, by phobias, paranoia and fear of sleep, attributed to a hypothesized "death anxiety"[25]. Jacques[26] has proposed that characterologically healthier individuals have mastered the anxiety associated with awareness of death at a relatively earlier age than those with personality dysfunction, who might be blocked from acknowledging the inevitability of death until overwhelmed by it. Recently, there has been a renewed interest in psychotherapeutic work with the elderly, most proponents of which argue that change and growth is possible[25–27]. In the view of Neugarten[28] and Costa[29,30], personality is the critical factor in adaptation to old age.

ASSESSING THE AGING PERSONALITY

Overview of Methodological Issues

Assessing personality in the elderly is a daunting task. Each of the three basic approaches cited above carries not only its own set of assumptions but its own limitations as well. The dimensional scales have restricted clinical relevance and yield abstract, somewhat reductionistic information about the individual. On the other hand, categorical diagnoses have been criticized as culture-bound and arbitrary[3], failing to "cut nature at its joints". DSM criteria, in particular, may be age-biased. Axis II criteria frequently appear to be addressing the concerns of a modal young adult, one who is expected to be establishing career and life-partner choices. If personality disorders "become less obvious in middle or old age", this may occur because Axis II does not relevantly assess the present-day experiences and behaviors of aging persons. Age bias could easily result in an underestimation of pathology, whereby symptoms are dismissed as "normative" for age. Overestimation of pathology is also possible, for example with dependency phenomena, where the realistic needs of an older person might be inappropriately viewed as symptomatic.

Psychoanalytic approaches have contributed to the study of personality and aging by encouraging the formulation of developmental theories for the second half of life. However, personality investigation of this type is focused on the individual patient, and its validity is ultimately predicated on a thorough knowledge of a few individuals; McHugh and Slavney have termed this "meaningful construct" validity[31]. While such models may explain how a patient's unique vulnerabilities and life circumstances interact to produce symptoms, large-scale empirical replication is impossible.

State–Trait Problems and Co-morbidity

Whichever theoretical–methodological model is used, the finding of age effects in personality study is frequently subject to the suspicion that they are not in fact true age effects, but rather reflect dysthymic, post-depressive or organic contaminants. This is the state–trait confound, a term that usually refers to the exaggerated self-report of some personality traits owing to the depressed state[32,33]. For example, recovered elderly depressives have been found to have more lifetime personality dysfunction than other elderly subjects[19], and in another study, twice as many recovered elderly depressives met full criteria for DSM-III-R personality diagnoses than did normal controls[20]. While recovery from depression in these studies was carefully documented, and no personality testing was carried out during symptomatic periods, it is impossible to completely rule out depressive

influences in clinical personality assessment. The problem is especially evident in geriatric populations, in which some forms of chronic depression seem to be closely related to personality disorders. Dysthymia, a low-grade depressive syndrome appearing in as much as 15% of the geriatric population[34,35], could equally well be deemed an affective disorder with prominent character pathology, or a personality disorder with secondary affective symptomatology; there may in fact be subgroups of each, defined by response to antidepressant drugs[36].

Another chronic depressive disorder often seen in the geriatric population, also associated with significant personality psychopathology, is "double depression". Post[37] used the term "depressive invalidism" to describe "double depression" in the elderly, referring to a group of geriatric patients having severe recurrent depression with incomplete remissions. Finally, the term "masked depression" has been used to describe a depression syndrome, believed to be more common after mid-life, in which cognitive or somatic symptoms are more prominent than sadness, tearfulness, or other affective manifestations[38]. Masked depression may not only present as a mixed personality disorder in geriatric patients, but has also been associated with a number of dysfunctional premorbid personality traits[39,40].

In addition to these chronic depressive entities, anxiety states and disorders also have considerable co-morbidity with personality disorders and have been shown to strongly influence personality assessment[41,42]. Co-morbidity of personality dysfunction and Axis I disorders covers a wide range in geriatric patients and, as with younger patients, the relationship may take different forms. Personality disorders may variously predispose to Axis I disorders, may represent subclinical prodromes of Axis I disorders, may have a pathoplastic or interactional effect with depression or schizophrenia, or may appear as a complication or "scar" of an Axis I condition[43].

The Problem of Organicity

Behavioral change can occur in the context of organic brain pathology or with the use of a variety of medications, situations common in geriatric populations. However, it is not clear whether such behavior should be regarded as dysfunctional personality change or organic pathology. The approach of DSM-III-R was to categorize demented patients' symptoms concerned with the quality of affect and its regulation as an "Organic Personality Syndrome", while reserving the more purely cognitive symptomatology for the diagnosis of dementia. Spitzer *et al.*[44] proposed in the work-group stage of the development of DSM-IV that the term "organic" be eliminated. In this proposal, dementia, delirium, and amnestic disorder would be listed together in a "Cognitive Impairment Disorders" category, while the other "organic" disorders, including personality, mood and anxiety, would be viewed as "secondary". This proposal was adopted, in principle if not in detail, by the final DSM-IV[63], with its use of category "Personality Change Due To . . .". The nosological reclassification of organic personality disorder to secondary personality disorder emphasizes the personality aspect by listing this entity according to phenomenology rather than etiology. Implicit in the concept of "secondary" personality phenomena is an acknowledgement that personality is subject to change caused by exogenous factors or brain pathology. However, a secondary personality disorder might still be relatively enduring and pervasive, have an interpersonal focus, and lead to significant behavioral impairment; all general criteria for the diagnosis of personality disorder would be met, except for that of early onset.

Self-report vs. Informant Data

Another technical difficulty in personality study common to all theoretical viewpoints is the discrepancy between self-report and informant data[21]. For this reason, reliance upon self-report may be a particularly flawed clinical or research strategy. Among some elderly persons, including control subjects for psychiatric research, an attitude of unrealistic optimism has been observed[45]. This tendency to recast the past in positive terms can be viewed either as a pathological refusal to acknowledge earlier disappointments and failures, or as a healthier attempt to reintegrate and reconcile the same experiences[46]. The state influences of depression, as noted earlier, would argue in favor of informant corroboration of self-report personality data. Similarly, even the subtle cognitive impairment of early dementing illness would seriously reduce the value of self-report personality data. But who should be the informant? Adults who knew an elderly subject as a young child may no longer be alive, and adult children have not necessarily witnessed their parents' young adulthood; even then, their childhood memories might present a distorted picture. Probably it is necessary to have multiple informants, including, where possible, siblings and contemporaries of lifelong acquaintance, in order to provide the most meaningful long-range information about personality functioning.

Time-frame Considerations

Since personality is by definition concerned with established traits, or relatively enduring aspects of motivational or interpersonal behavior, over what periods of time should changes persist in order to be deemed new traits? In the clinical context, all versions of the DSM are vague on this point, stipulating that criteria for personality disorders should reflect current (past year) and long-term functioning, but not clearly requiring that symptoms be present continuously from adolescence to old age in order to qualify for a personality disorder diagnosis[7]. Also, there is no real provision for past personality disorders, those that have been present throughout much of adult life but are attenuated in old age, or for late-onset personality disorders, those first appearing or meeting full criteria in middle age or later. Recently developed standardized instruments for Axis II diagnoses may eventually produce better information on the natural course of personality disorders and the prevalence of past and late-onset disorders[46]. For the moment, it is left to the clinician to select an appropriate time frame for making a personality disorder diagnosis and to determine whether current behavior reflects personality functioning, affective state, organic brain changes, adjustment reaction to age-related life events, or a combination of these factors[47].

Outcome Measures

Assuming that a suitable set of dimensions, categories or developmental milestones can be selected for personality investigation in the elderly, against what outcomes might they be expected to co-vary? Satisfaction with life, a sense of global well-being and health concerns have seemed to some authors to be the most important outcome dimensions to evaluate in older people, because they are indicators of the quality of life[48–50]. Longitudinal investigation suggests that, overall, well-being tends to be stable over time, probably because the frequency and intensity of both positive and negative emotions decline with age[48]. However, associations between specific

personality dimensions or categories and life satisfaction in old age have not been established. At the other end of the adjustment spectrum, it has already been noted that depressed elderly patients have had abundant lifetime personality psychopathology[19,20]. In a sample of completed suicides over age 60 years, 45% were estimated to have an Axis II disorder based on interviews with close relatives[51]. Nevertheless, it is not always intuitively clear what constitutes adaptive or maladaptive personality functioning in old age. For example, a relatively greater degree of risk-taking or sensation-seeking traits could be viewed as adaptive in a 20-year-old than in an elderly person; the older individual should optimally have some sensation-seeking behavior but could obviously be placed in situations of unreasonable risk without some reduction of sensation-seeking intensity. Interestingly, recovered elderly depressives have been found to have a greater preference for environmental stimulation, as suggested by higher scores on the Sensation-Seeking Scale[52,53] than normal elderly controls[53], implying a complex interaction among aging, trait preference for environmental stimulation, and affective illness.

Assessment of DSM Criteria in Geriatric Patients: Clinical Notes

The diagnosis of personality disorders requires evidence of symptomatic behavior, both currently and in the past; when examining the current period of old age for evidence of personality disorder criteria, it is necessary to interpret those criteria in a geriatric context. For example, in the odd–eccentric (Cluster A) personality disorders, including paranoid, schizoid and schizotypal personality disorders, suspiciousness of exploitation or harm (a criterion of paranoid personality disorder) or social and sexual isolation (a criterion of schizoid personality disorder) should be carefully weighed against realistic dangers and social limitations faced by the older person. For this, an informant who knows the patient well is often required.

Cluster B, the dramatic–emotional personality disorders (antisocial, borderline, histrionic and narcissistic), are assigned to geriatric patients especially infrequently, possibly because they are truly "immature" syndromes that prove unstable over long periods of time, and probably also because much latitude is necessary to fit the criteria to the experiences of geriatric patients. For example, evaluation for the borderline criterion of "idealization" should include consideration of such behavior when directed toward caregivers in a hospital or nursing home. Similarly, "self-damaging impulsiveness" need not be limited to reckless driving or sexual activity, as suggested by DSM-III-R, and "frantic efforts to avoid real or imagined abandonment" should not be confused with reactions to age-related losses or institutionalization. Thus, criteria such as "self-damaging impulsiveness" might be broadened to include the geriatric context, while other criteria, such as "frantic efforts to avoid abandonment", should be narrowed to account for the impact of realistic events.

Interpretive flexibility is also needed to assign Cluster C personality disorder diagnoses to elderly patients. Reactions and attitudes toward caregivers provide an appropriate context for many elderly patients in which to interpret Cluster C criteria, particularly those for passive–aggressive and dependent disorders. However, medical illness can transiently exacerbate dependency phenomena. For all of these disorders, it seems most appropriate to err on the side of conservatism or specificity in diagnosis. Obviously, the clinician can be most confident of the assessment when antecedents of criteria are traceable to the past, but there remains an obligation to determine what is or is not pathological in the older person's present reality.

TREATMENT OF ELDERLY PATIENTS WITH PERSONALITY DISORDERS

There is virtually no research data to guide the comprehensive treatment of elderly patients with personality disorders. However, based upon classic and recent writings in this area[23,25–27] and treatment reports in younger age groups, it is possible to set forth some general principles of management.

Co-morbid Axis I Disorders

It has already been noted that the depressed state may influence the assessment of personality disorders. It may also be true that, especially in the elderly, personality disorders exert their most clinically meaningful effects in the setting of major depressive disorder. For example, earlier onset of depression as well as greater severity and frequency of depressive episodes, have been found in elderly patients with personality disorders[2,38]. Personality disorder symptoms also appear to affect elderly patients' attitudes and behaviors toward antidepressant treatment. Personality-disordered patients have difficulty in establishing positive therapeutic alliances with psychotherapists and general physicians, a factor which in turn promotes poor adherence to either psychopharmacological or psychotherapeutic treatments. Finally, while personality dysfunction may not lengthen the depressive episode itself, in interaction with residual depressive symptoms, it appears to prolong depression-related declines in global functioning and quality of life[59].

Thus, it may be reasonable to address co-morbid Axis I conditions, particularly affective or anxiety disorders, before planning any treatment efforts directed specifically toward the personality component. In conditions such as dysthymia, where personality dysfunction and affective symptomatology at times seem to merge, it may also prove useful to defer long-term treatment planning and psychosocial decision-making until somatic treatments have reached maximum efficacy. Likewise, medical conditions that might affect the course of personality symptomatology should be fully evaluated.

Pharmacotherapy

Pharmacotherapy for geriatric personality disorder patients has not been investigated *per se* and remains an underdeveloped area. In younger age groups, there exists an older literature for borderline personality disorder, in which psychotic-spectrum symptomatology was shown to be more effectively treated by neuroleptic medication than placebo[54], and amitriptyline was usually more effective than placebo but no more effective than haloperidol in antidepressant effect[55]. MAO inhibitors[56], lithium[57] and carbamazepine[58] were proposed to have limited usefulness for specific traits or symptoms. More recently, there have been some studies in mixed-age populations showing modest effects of particular medications or medication classes on the symptomatology of the three Axis II clusters. For example, haloperidol and thiothixene have been found to be useful in the treatment of patients with schizotypal or other Cluster A personality disorders, especially the transient paranoia, agitation or rages associated with these disorders[60]; the selective serotonin reuptake inhibitors (SSRIs), fluoxetine and sertraline have shown some promise in treating impulsive, self-injurious and depressive behaviors associated with Cluster B personality disorders[61], and fluoxetine and MAOIs have been found to decrease the kind of avoidant behaviors found in individuals with Cluster C personality disorders[62].

Psychotherapy

Unless there is a co-morbid Axis I disorder that requires psychopharmacological intervention, the treatment of geriatric personality disorders is largely a psychotherapeutic endeavor. As described by Sadavoy[27], a major difference between the psychotherapy of older and younger patients is the time frame covered. Transference issues continue to be directed from childhood sources and early[8] parental relationships, but they will often contain an overlay from experience later in life. Usually the initial focus should be on the patient's present reality and presenting problems, secondarily on historical material and on the relationship with the therapist. Then, as it unfolds, more time and effort can be devoted to clarifying and perhaps analyzing distortions in the patient's attitudes and behaviors toward the therapist. Some patients, not necessarily the highest-functioning ones, will be able to focus usefully on the relationship with the therapist to a greater degree than others. In either case, special attention must be paid to the potential for transference issues to become painful and paralyzing for both patient and therapist. Ideally, discussion of the therapeutic relationship can provide a point of shared reality, which patient and therapist can examine together. Issues from the past then emerge more naturally, in an unforced and relevant fashion. Patients probably do have a need to mourn past losses, a process that can be fostered in psychotherapy, but it should be remembered that such mourning is not done globally or in a predictable sequence[27].

Another factor complicating psychotherapy in the elderly is that overall treatment plans often involve family, caregivers or institutional representatives. Important persons in the patient's social sphere must be engaged in treatment strategies because of the interpersonal field in which personality psychopathology, especially the Cluster B disorders, is expressed; also, older people with disabilities may function less autonomously. This creates potential boundary problems for the therapist, as well as concerns about confidentiality; these must be spelled out to the patient and an understanding reached between the patient and therapist on exactly what information may be transmitted to others and under what circumstances this will be done. Once this is accomplished, creative use can be made of family and institutional supports.

Whatever the approach taken in psychotherapy, limited and realistic goals should be set, based upon a collaterally informed picture of the patient's long-term functioning. A psychotherapy relationship cannot reasonably be expected to resolve the psychological deficits, and the consequences of those deficits of the elderly personality disorder patient—a lifetime of failed relationships, missed opportunities and unused talents. Nevertheless, it can be hoped that for some individuals, the loss of narcissistic gratifications associated with physical beauty and vocational competence can actually foster psychotherapeutic work. Patients may find themselves in old age to be motivated for self-examination as never before. The impetus provided by aging and the press of reality may render the older patient amenable to a process of growth and change.

Alcohol Abuse in the Elderly

Helen H. Kyomen[1] and Benjamin Liptzin[2]

[1]*McLean Hospital, Belmont, MA, and* [2]*Baystate Medical Center, Springfield, MA, USA*

Alcohol abuse in the elderly may be defined as the persistent and intended use of ethyl alcohol despite the problems caused by its use[1,2]. In the elderly, alcohol abuse usually presents clinically as self-neglect, falls, confusion, lability, depression, unusual behavior, injuries, diarrhea, malnutrition, myopathy, incontinence or hypothermia[3,4]. In fact, the elderly person with alcohol abuse problems may be hospitalized for any one of these problems. During the course of the hospitalization, one may uncover signs of characteristic addictive use of ethyl alcohol, with: (a) tolerance; (b) withdrawal symptoms; (c) loss of control of use; (d) social decline; and (e) mental and physical decline[5]. Alcohol abuse in the elderly is an under-recognized problem that has become increasingly important due to the growing numbers of elderly people[6–10]. Prevalence estimates of alcohol-related problems are in the range 1–6% in community-dwelling elderly, 7–22% in medically hospitalized elderly, and 28–44% in elderly psychiatric inpatients[1,4]. In one study of older primary care outpatients, 15% of men and 12% of women regularly drank in excess of limits recommended by the National Institute of Alcohol Abuse and Alcoholism (> 7 drinks/week for women and > 14 drinks/week for men)[11].

EFFECTS OF ALCOHOL IN THE ELDERLY

Older people are at greater risk and more vulnerable to the toxic effects of alcohol for three main reasons:

1. A smaller volume of alcohol is required to produce the same effects as in a younger person. The elderly have a decreased volume of distribution due to decreased muscle mass, a greater proportion of fat and a smaller water compartment. These all result in a higher blood alcohol level than in a younger adult for the same amount of alcohol consumed[12–16]. This suggests that the elderly person's brain, liver, cardiac and other organ systems are subjected to a greater toxic effect from a given amount of alcohol. In a younger person, larger amounts of alcohol consumption may be necessary before detrimental effects from alcohol abuse become grossly evident. An elderly person may reach this threshold for hazardous use of alcohol after drinking a relatively small amount[17].
2. The general decrease in the capacity to withstand stress and maintain homeostasis, as well as a higher risk for medical illness and disability in elderly people, can magnify the effects of alcohol abuse in the elderly.
3. Some organ systems may be especially susceptible to alcohol in the elderly. For example, the central nervous system appears to be more sensitive to alcohol in the older person[18–21], and bone fractures are much more frequent among elderly who use alcohol than in those who do not[22].

The interaction of these three main factors places the elderly alcohol-using person at greater risk for multiple impairments resulting from the use of alcohol.

There are many possible detrimental effects from alcohol abuse in the elderly. Among them are the following:

1. Driving ability can be adversely affected with the consumption of minimal amounts of alcohol. Relatively small amounts of alcohol can lead to confusion, visuospatial impairment, problem-solving deficits and motor impairment in the elderly[23–25], which can inhibit the continuous attention and quick responses needed for driving. If the elderly person also has cognitive or sensory deficits, then the additional insults from alcohol use may make driving considerably more dangerous[17,20].
2. Cognitive impairments suggesting dementia may be caused by alcohol abuse[26,27]. Although some cognitive impairment can result from even social drinking, chronic alcohol consumption has been shown to cause marked cognitive deficits, with associated cortical atrophy and ventricular dilatation on brain scan[19,28,29]. Some researchers have suggested that alcoholism contributes to accelerated mental aging, but this is still controversial[19,30].
3. Elderly alcoholics have a higher prevalence of alcohol-related medical conditions than the elderly population at large. Such conditions include alcoholic liver disease, alcoholic cardiomyopathy, hypertension, chronic obstructive pulmonary disease, neurologic diseases (including cognitive brain syndromes and peripheral neuropathy), malnutrition, osteopenia, psoriasis, peptic ulcer disease and various cancers[22,31–36].
4. Alcohol use can adversely affect the elimination of some drugs and add to the toxicity of others. This places an elderly person with medical illness or disability who is taking prescription medication at great risk for having subtherapeutic or adverse effects from the medication[37,38]. The magnitude of this problem is evident when one considers that the elderly receive 25% of all drugs prescribed in the USA, while comprising only approximately 12% of the population[6,39,40,41].
5. The depressant effects of alcohol on the central nervous system may mimic or contribute to depression in the elderly[42,43]. Some elderly with depressed mood may resort to drinking in order to "self-medicate" themselves. This may alleviate the depressive symptoms initially, but later lead to an increase in depression, anxiety, sleep disturbances and impotence[40,44].
6. Alcohol can contribute to malnutrition in the elderly. Malnutrition can result from the interaction of the following factors[45,46]:
   (a) Food intake can be hindered if the elderly alcoholic develops depressed mood, becomes apathetic and experiences

loss of appetite. If the elderly alcoholic's impaired ambulation results in a reduced capacity to obtain food, or if limited financial resources are used to purchase alcohol instead of food, dietary intake may be restricted further.
(b) The effect of alcohol on the gastrointestinal tract is to produce malabsorption of fats, fat-soluble vitamins, calcium, magnesium, iron and zinc. The active transport of B vitamins is also impaired.
(c) Alcohol can contribute to increased losses of magnesium, phosphate, potassium and zinc through the urine. If vomiting and diarrhea occur, there may be increased loss of sodium, potassium and chloride.
(d) Alcohol use increases the requirements for folate and pyridoxine.
7. Alcohol use contributes to accidents and injuries that may lead to fractures or subdural hematomas. A study of accidental drowning in Denmark found that between one-third and one-half of adult drownings were related to alcohol intake[47].
8. Alcohol use disorder has been associated with higher mortality in a study of older public housing residents[48].
9. Alcoholism can disrupt the elderly alcoholic's family structure and cohesiveness and may even lead to family violence. This can result in dysfunctional family relationships, with consequent increased difficulty in treatment of the alcohol-related problems.

Despite the many unfavorable effects of alcohol abuse in the elderly, researchers have also reported positive aspects of alcohol use. Moderate alcohol consumption has been associated with a decreased risk of ischemic stroke in elderly subjects[49]. A study of elderly Australians found that alcohol intake was associated with a significant increase in life expectancy[50].

CHARACTERISTICS OF ELDERLY ALCOHOL ABUSERS

Elderly alcohol abusers differ from younger alcohol abusers in a number of ways. Alcohol abuse in the elderly is often associated with a clustering of events, which are common in late life. These include such occurrences as job retirement, widowhood, the deaths of close friends and relatives, more medical illness and disability in oneself and one's peers, and perceived loss of a meaningful role or function. Some authors consider late-onset alcoholism to be "reactive alcoholism", where the dependence on alcohol is initiated by a need to alleviate the stresses of undergoing multiple losses. However, the extent to which alcohol abuse in the elderly is precipitated by stress from these losses is unclear. Some researchers have found little change in alcohol consumption or drinking behavior due to life stressors[51,52].

The time of onset of alcohol abuse may also significantly differentiate the younger alcoholic from the older one. Early-onset alcoholics have a greater amount of psychopathology and family history of alcoholism than late-onset alcoholics. Early-onset alcoholics are characterized by being male relatives of alcoholic men with histories of violence with and without alcohol, legal problems due to alcohol use, and illegal substance abuse. Late-onset alcoholics are characterized by having isolated alcohol-induced problems with health, marital relationships or self-care, and much reduced histories of arrests, violence or other substance abuse. Many elderly people with alcohol problems fall into the late-onset alcoholic group. These findings suggest that the etiology and predisposition of a person to an alcohol use disorder may differ by onset age. If this is so, the treatments and interventions for an alcohol use disorder may also differ with age of onset and need to be individualized accordingly[53,54].

Individual feelings towards alcohol use are affected by the cultural and historical attitudes one grows up with. For example, the experience of the American elderly alcoholic may differ from that of younger alcoholics in that the elderly alcoholic and his peers may have been exposed to the turmoil of the Prohibition era. The moral issues highlighted in this historical period may influence the willingness that some elderly may have in recognizing and accepting a diagnosis of, and treatment for, alcoholism.

THE RECOGNITION OF ALCOHOL ABUSE IN THE ELDERLY

Alcohol abuse in the elderly often comes to the attention of health professionals through presentation with a non-specific medical or psychiatric symptom, such as self-neglect, falls, confusion, lability, depression, unusual behavior, injuries, diarrhea, malnutrition, myopathy, incontinence or hypothermia. In cases where alcohol abuse is suspected, alcohol dependency must be considered. Alcohol dependency is suggested when there are: (a) tolerance; (b) withdrawal symptoms; (c) loss of control of use; (d) social decline; and (e) mental and physical decline.

Tolerance to alcohol may be assessed by establishing a reliable history of the patient's drinking pattern. Corroboration from family members and others close to the patient may be crucial. Tolerance is suggested if the patient exhibits a quantity and frequency of drinking which is increased over his baseline pattern of drinking. A patient with tolerance to alcohol will require a greater quantity of alcohol to achieve the same amount of inebriation that a lower quantity had been able to achieve previously. Tolerance is strongly suggested if there has been at least a 50% increase in the amount of alcohol required to attain a given effect, a blood alcohol level of 150 mg without intoxication, or the equivalent use of one-fifth gallon (750 mg) of alcohol or more in 1 day by a 180 pound person[55].

Withdrawal symptoms occur when a patient who is tolerant to alcohol experiences a rapid decrease in blood alcohol concentration. Symptoms of the alcohol withdrawal syndrome include tachycardia, with a pulse of greater than 110 beats/min, tachypnea, hypertension, low-grade fever, sweating, nausea, vomiting, hand tremors and increased anxiety. In some cases, the patient may develop seizures or delirium tremens with confusion, agitation and visual hallucinations. An elderly patient undergoing withdrawal may experience one or all of these symptoms[55,56].

Loss of control means that the patient is no longer able consistently to choose the amount of alcohol he/she will consume in a given situation. He/she may also experience blackouts and behave and feel in unpredictable ways[55].

Social decline in the elderly alcoholic is assessed from a baseline of age-appropriate behaviors[55]. Many elderly people no longer hold a steady job, do not drive or hold a driver's license, and have lost many of their close friends and associates with whom they used to socialize. Thus, it may not be as appropriate to assess for social decline by investigating these areas of the elderly patient's life as it would be in a younger patient. However, it is relevant and revealing to ask elderly people whether they are in contact with their children or grandchildren, and to what extent. It is also useful to find out whether the patient's relatives express any concern about the patient's alcohol use. Investigating the patient's functioning with respect to his/her hobbies or other enjoyed activities can also be useful.

Physical, psychological and laboratory findings may also uncover problems with alcohol use[55]. Addictive alcohol use can lead to malnutrition, gastrointestinal upset and bleeding, delirium, falls, depression, hypertension and neglect of self. Recurrent diseases of the stomach, pancreas or liver may also be caused by excessive alcohol abuse. These medical conditions often bring the

elderly alcoholic to clinical attention. Laboratory results of macrocytosis, elevated mean corpuscular volume, and increased liver enzyme levels, especially γ-glutamyl transpeptidase, may correlate with alcohol abuse in the elderly. Blood alcohol levels, and urine or breath tests for alcohol, may be used to confirm alcohol intoxication.

Assessment of tolerance, withdrawal, loss of control, social decline and mental and physical decline are useful clinical parameters to recognize and diagnose alcohol addiction. Several screening instruments have been devised to help clinicians recognize alcoholism. These scales typically assess the quantity and frequency of drinking, social and legal problems resulting from alcohol abuse, health problems related to excessive alcohol use, symptoms of addictive drinking, and/or self-recognition of alcohol-related problems[57–59]. Many of these instruments have been validated for younger populations, but not specifically for the elderly. The validity of the CAGE screen for alcoholism in the elderly has been examined empirically[60]. ''CAGE'' is a mnemonic for the questions: Have you ever felt a need to Cut down on drinking? Have you ever felt Annoyed by others inquiring about your drinking? Have you ever felt Guilty about drinking? Do you ever use alcohol for an Eye-opener? If two or more of these questions are answered positively, a need for more extensive evaluation for alcohol abuse is indicated. Another more detailed screen is the Michigan Alcoholism Screening Test–Geriatric Version (MAST-G)[61]. In addition, the original MAST, scored with weighted (MAST) and unit scoring (UMAST), and two shorter versions, the Brief MAST (BMAST) and Short MAST (SMAST), have been tested in the elderly[62]. Researchers found that the MAST and UMAST gave excellent sensitivity and specificity for alcohol abuse in the study population of 52 hospitalized elderly male alcoholics, matched with 33 non-alcoholic controls. The MAST and UMAST may be useful screening instruments to help recognize alcoholism in the elderly.

THE TREATMENT OF ALCOHOL ABUSE IN THE ELDERLY

Once the diagnosis of alcohol abuse is confirmed, the first step in treatment is a thorough evaluation to identify any other coexisting medical or psychiatric problems. Treatment for these problems must be initiated at the same time as the patient is detoxified. Providing adequate nutrition and hydration is especially important in the elderly alcoholic, due to increased nutritional problems and impaired thirst mechanisms in the elderly. Benzodiazepines are generally avoided in the detoxification of elderly alcoholics, due to their potential for causing delirium. However, if significant withdrawal symptoms occur, benzodiazepines should be administered[56,63,64]. Elderly patients may experience more severe withdrawals from alcohol and require higher doses of benzodiazepines than younger patients. In general, detoxification with benzodiazepines with a short half-life is recommended in the elderly. However, these medications may not provide adequate anticonvulsant effect and the use of longer-acting benzodiazepines may be necessary[56].

Once the elderly alcoholic patient is detoxified, adequate relapse prevention and rehabilitative treatment is crucial for the patient to maintain sobriety. The elderly alcoholic must first come to an acceptance of his/her alcohol abuse problem. Family members or others who are close to the patient may be able to help the patient break through the denial regarding alcohol abuse seen in many alcohol abusers. Family members may also be instrumental in motivating the patient to stop drinking. Patient and family education about the effects of alcohol must be provided, and the need to abstain from alcohol must be stressed. A behavioral and self-management treatment module has resulted in marked success in treating alcohol use problems in the elderly[65]. This module educates the elderly alcoholic about drinking behavior, the acquisition of self-management skills, and the re-establishment of social networks.

The elderly alcoholic patient's recovery and rehabilitation is an ongoing process. The patient needs to learn to readjust to life without alcohol. The patient's family and close relatives and friends can help him/her in this endeavor by supporting sobriety in the patient and incorporating the non-drinking patient into their lives without the presence of alcohol. Family members may have been ''enabling'' the patient to drink, and they need to be made aware of these patterns of behavior and change them through family education and family therapy. If the elderly alcohol abuser is a parent and the enablers are his children, the role reversal that is inherent in the children's setting limits on their parents may make this task especially difficult. Group therapy may help the patient adjust to a non-alcoholic lifestyle. In this setting, he/she can develop non-alcohol-related social skills and learn to bond with others in safe surroundings, free of the context of alcohol. If elderly alcoholics can be treated in age-specific groups, they may remain in treatment significantly longer and be more likely to complete treatment than those treated in mixed-age groups[65]. Involvement in Alcoholics Anonymous with people with whom the patient feels comfortable and can consider his/her peers is important, especially if he/she has no close relatives or friends. The relationships with others that can be formed in these settings can provide a replacement for the alcohol to which the patient was bonded previously. Family involvement with the patient in Alcoholics Anonymous and in other affiliated groups such as Alanon, Alateen or Alatot is also important, as alcoholism adversely affects family members who also need support, education and treatment.

Use of alcohol-deterrent medications, such as naltrexone or disulfiram, may serve as adjunctive treatments. These drugs may help motivated alcohol abusers to reduce the quantity of alcohol used or the number of drinking days. However, these medications generally are not effective unless prescribed and monitored as part of an overall, multidisciplinary treatment and relapse prevention plan. Opioid receptor antagonists, such as naltrexone or related compounds, may be less toxic than disulfiram in elderly patients[66–68].

The cultural aspects of alcohol abuse intervention are also worthy of consideration. The above recommendations for treatment are a description of treatment conceptualizations in the USA. These interventions may need to be modified for other countries. In instituting any type of treatment or intervention, it is important to consider the context of the problem being addressed and the context into which the treatment or intervention will be instituted. The consumption of alcohol can take on a variety of cultural meanings. To some groups, ethanol is a food or is associated with religious rituals. For others, it is a means to relax and calm one's nerves. For still others, alcohol is considered to be a sinful intoxicant used by those of weak moral fiber. To intervene most effectively with an aged person for whom alcohol consumption has become a problem, it is important to understand what meaning the use of the alcohol has for him as an individual, a family member and as part of the greater society, including his cultural group. The contextual meaning of the change in alcohol use must likewise be considered. To understand these contextual meanings most effectively, the clinician must be aware of what his/her inherent assumptions may be about these contextual meanings and try not to confound with his/her own biases his/her understanding of the situation. Members of the patient's contextual and cultural groups may be very helpful in providing meaningful insights into these understandings. Once these cultural factors are understood, interventions to reduce the problematic alcohol consumption to the desired outcome of abstinence or

perhaps of less harmful alcohol use, can be creatively formulated and instituted more effectively and efficiently.

CONCLUSION

In summary, alcohol abuse in the elderly is a significant problem that needs to be addressed aggressively. Recognition and diagnosis of alcohol abuse may be more difficult in the elderly. The biological and psychosocial losses and decline that are often used to identify alcoholism in younger people can occur in many elderly who do not abuse alcohol. The clinical presentation of an elderly alcoholic is often with a medical condition that may be masked by other medical diagnoses. For these reasons, the clinician must be especially alert to the possible presence of alcohol abuse in this age group. If alcohol abuse is identified, the clinician must then be prepared to direct or initiate treatment in a culturally appropriate, sensitive, flexible and creative manner that is geared to the elderly individual and his/her family and significant others.

Epidemiology of Alcohol Problems and Drinking Patterns

Celia F. Hybels and Dan G. Blazer
Duke University Medical Center, Durham, NC, USA

A key finding from the Epidemiologic Catchment Area (ECA) community studies of adults 18 or older conducted in the USA two decades ago was the high prevalence of alcohol use and dependence, as defined by DSM-III criteria[1,2]. The lifetime prevalence of alcohol abuse/dependence in the ECA sample was 13.8%. Gender differences were significant. Among men, the lifetime prevalence was 23.8%, while among women the prevalence was only 4.6%. Age differences in lifetime prevalence were noted for both males and females. The lifetime prevalence of alcohol abuse/dependence for men in the ECA was lowest in those 65 or older (14%) compared to 21% in those ages 45–64, 28% in those ages 30–44 and 27% in those ages 18–29. The 1 month prevalence among men 65 or older was 1.93%. A similar decreasing prevalence with age was seen in women, with a lifetime prevalence of 1.49% in women 65 or older and a 1 month prevalence of less than 1% (0.4%).

While the proportion of elderly with defined alcohol abuse or dependence may appear low, alcohol consumption at any level may potentially be problematic in older adults. Because of decreased lean body mass and smaller volume of distribution, higher peak ethanol concentrations per dose are found in older compared to younger subjects[3]. Also, even in small amounts, alcohol may exacerbate or mask symptoms of illness. Finally, many elderly are users of both prescription and over-the-counter medications that may interact with alcohol[4]. As the numbers of elderly will increase significantly over the next several decades (as the post-World War II generation ages) and alcohol use rates are not likely to decrease, alcohol use in older adults is an important public health concern. In addition, females are increasing their rate of alcohol use and make up a larger proportion of the elderly, potentially resulting in increased prevalence overall[5].

Recent reviews have focused on the epidemiology of alcohol use among older adults[6–11]. These reviewers have concluded that alcohol use in older adults in excess of recommended limits is an important clinical issue. Chermack *et al.*[12] examined the relationship between alcohol consumption patterns and the presence of DSM-III-R alcohol symptoms among 443 current drinkers, 55 years of age or older, and found that both average daily consumption and days of heavy drinking in the past year independently predicted symptom status. Consumption levels for men and women were only different for problem drinkers. The authors suggest that their results support the recommendation that moderate consumption levels should be lower for older than for younger adults, with a recommendation not to exceed one drink/day.

The prevalence of any alcohol use and the prevalence of heavy drinking among elders, as well as the factors and outcomes associated with drinking, are addressed below.

PREVALENCE OF ALCOHOL USE

The prevalence of alcohol use has been shown in cross-sectional studies to decline with age[13–17]. Early studies in the USA noted this age difference[13,14]. In 1968, Cahalan and Cisin[13] conducted a national survey of drinking practices in the USA using a representative sample of 2746 persons aged 21+, and reported the prevalence of alcohol use declined with age. Among adults aged 60+, 65% of the males and 44% of the females drank alcohol within the past year. The prevalence was lower than that observed in younger males (84% in men aged 21–29 and 86% in men 30–39) and in younger females (70% in women 21–29 and 72% in women 30–39). In a probability study of adults living in western New York, conducted 25 years ago, the prevalence of alcohol use was lower in persons aged 60 or older than in those under 60, and the proportion of adults with alcohol-related problems was much less in those 60+. The proportion of moderate and heavy drinkers was also lower among those aged 60+ than in those younger. Only 7% of those aged 60+ were heavy drinkers, compared to 24% of those aged 50–59 and 30% of those aged 18–49[14].

Recent studies have confirmed these earlier findings. The prevalence of alcohol use in the past year among persons aged 55+ participating in the National Longitudinal Alcohol Epidemiologic Survey was 29.5%, and there was an inverse relationship between alcohol use and increasing age[15]. In the 1988 Alcohol Supplement of the National Health Interview Survey (NHIS), the prevalence of alcohol use, defined as 12 or more drinks in the past year, was 60.9% in those aged 18–29, 58.3% in those 30–44, 47.3% in those 45–64 and 30.4% in those 65+. The prevalence of lifetime abstainers in those aged 65+ was 30.8%, compared to only 17.9% in those 45–64 and 13.1% in those 30–44. The prevalence of lifetime infrequent drinking and former drinking also increased with age[16]. Ruchlin used data from the 1990 Health Promotion and Disease Prevention supplement to the National Health Interview Survey to examine prevalence of alcohol consumption in adults aged 55+. A total of 46% reported that they had consumed alcohol during the past year. The study found a continuous decline across age groups, from 52.9% of those aged 55–64 categorized as current drinkers within the past year, compared to 24.7% of those aged 85+. Of the sample aged

55+, 17% reported that they had consumed alcohol every day in the past 2 weeks. In controlled regression analyses, more people aged 65–74 drank every day, compared to those 55–64 (OR = 1.36), but people aged 75+ drank less than those 55–64. Males and Whites used alcohol more frequently and were more likely to be heavy drinkers than females and non-Whites. The lower one's perceived health status, the lower the odds of drinking every day. Believing excessive drinking increases the chances of getting cirrhosis of the liver decreased the odds of moderate and heavy drinking[17].

There are various explanations why the prevalence of alcohol use is lower in the elderly. Selective survival may be a factor, in that persons who drink are less likely to survive to older ages. Cohort effects are also possible. Persons who grew up in the era of Prohibition and economic depression prior to World War II may have had lower alcohol use throughout their lives[5]. Studies have also shown that some elderly decrease their use of alcohol as they grow older. Barnes found half of the subjects aged 60+ who were current abstainers reported that they were former drinkers, with "bad health" most often given as a reason for giving up drinking[14]. Busby *et al.*[18] investigated alcohol use in a community-based sample of adults aged 70+ in New Zealand. Both frequency and quantity of intake decreased with age. A total of 60.1% of the men and 30.3% of the women said they drank less compared to middle age, and only 7.4% of the men and 11.1% of the women said they drank more. The main reasons cited for decreased use of alcohol were change in health and fewer social opportunities, with reasons cited for increased intake being more time and money[18]. Similarly, a significant proportion of male current drinkers, but not abusers, selected from medical admissions aged 65+ in the UK reported heavier drinking in the past. The most frequent reasons given for reduction in intake were onset of ill-health (36%), loss of social contact (28%) and financial difficulties (19%)[19].

Using data from the Normative Aging Study, Glynn *et al.*[20] studied generational effects on alcohol consumption in a sample of 1859 male adult volunteers interviewed at baseline and 9 years later. Older men drank less than younger men at both assessments, yet there was no tendency for men to decrease their consumption levels over time. Each older cohort had a lower prevalence of problems with drinking than the next youngest cohort. The authors suggested that their results show that aging is not as important as generational changes in prevalence[20]. In contrast, Adams *et al.* followed a cohort of 270 healthy community-dwelling elderly aged 60+ over 7 years[21]. At baseline, the investigators found a decline in the percentage of drinkers with increasing age[22]. In the 7 year follow-up, there was a 2%/year decline in the percentage of subjects consuming any alcohol, but mean alcohol intake did not change for those who continued to drink, except among heavy drinkers, suggesting an age-related decline rather than a cohort effect[21]. Smart and Adlaf[23] pooled data from four cross-sectional surveys of adults in Ontario and found no dramatic changes in alcohol use between 1976 and 1984 among persons aged 60+. Elderly respondents were more likely to report abstention from drinking than those younger (40% of those aged 60+ compared to 15% of those 30–59 and 13% of those 18–29). Of the elderly respondents, 17% reported consuming five or more drinks in a single sitting, a much lower prevalence than among those 30–59 (44%) and those 18–29 (60%)[23].

Regardless of a decline with age, the prevalence of alcohol use in the elderly remains high. Meyers *et al.* found, in their study of the drinking behavior of 928 residents of Boston aged 60+, that 53% were abstainers, 26% had less than one drink/day, 16% one to two drinks/day and 6% two or more drinks/day[24]. In a sample of 270 healthy men and women aged 65–89 living in the southwestern USA, 48% of the participants reported in their 3 day diet record they had consumed alcohol, with 66% reporting that they consumed alcohol at least monthly[22].

The prevalence of alcohol use in the recently conducted multi-site Established Populations for Epidemiologic Studies of the Elderly (EPESE) studies of persons aged 65+ varied by site. In East Boston, 70.5% of the sample drank alcohol in the past year and 54.7% had used alcohol in the past month. Similar findings were reported from New Haven; 65.8% had used alcohol in the past year and 51.9% in the past month. The proportions were lower in Iowa and North Carolina. In the Iowa sample, 46.3% had used alcohol in the past year, while 31.2% had done so in the past month. In the North Carolina EPESE, 33.4% had used alcohol in the past year and 24.6% in the past month. Men were more likely to report use of alcohol in the past month than were women[25,26].

Samples from clinical populations have found similar proportions of high use. In one of the first studies done in the UK, Bridgewater *et al.* interviewed 101 patients aged 60+ from a general practice and found that 92% of the men and 77% of the women used alcohol[27]. Iliffe *et al.* studied 241 patients from general practice aged 75+ and found that 51% of the men and 22% of the women reporting using alcohol in the past 3 months[28]. Using data from the Liverpool Longitudinal Study of Continuing Health in the Community, Saunders *et al.*[29] reported, among 1070 men and women aged 65+ randomly selected from patient rosters, that 10.5% admitted to drinking more or less every day (17.7% men and 6.1% women). At the 3 year follow-up, one-fifth of the subjects were regular drinkers, drinking on at least one occasion per week[29]. Among a sample of 132 general hospital patients aged 65+ in Leiden, The Netherlands, the prevalence of alcoholism was 9% (13% among men and 7% among women)[30]. Callahan and Tierney[31] found the prevalence of alcoholism to be 10.6% among 3954 primary care patients aged 60+. Patients with alcoholism were more likely to be younger, have fewer years of education, and be male, Black, smokers and malnourished[31]. In a sample of 539 medical admissions aged 65+ in the UK, the prevalence of alcohol abuse was 7.8%. An additional 29.7% of the sample who were neither abstainers nor occasional drinkers nor alcohol abusers drank regularly; 42.9% of the men and 15.9% of the women[19].

In summary, research studies conducted in both community and clinical samples over the last several decades have consistently shown that alcohol use among older adults is not uncommon, and that over half of community-dwelling older males may consume alcohol on a regular basis. While the prevalence of use may be lower than that seen in younger populations, it is still not clear whether this is a cohort or an age effect.

PREVALENCE OF HEAVY DRINKING

Estimates of the prevalence of heavy use are also quite high in the elderly. Cahalan and Cisin reported from their community sample that 20% of the males and 2% of the females aged 60+ were classified as heavy drinkers[13]. Meyers *et al.*[24] found in their sample of Boston residents 60 or older that 1% were self-reported problem drinkers. All problem drinkers had long-term drinking problems and were less likely to be satisfied with their social relationships. While the proportion of problem drinkers was lower in those aged 75+ compared to those aged 60–75, the proportion of drinkers who report problems was similar for both groups[24]. Mirand and Welte studied a sample of community-dwelling adults aged 60+ in Erie County, New York, and found the prevalence of heavy drinking was 6%[32]. In their sample of 270 healthy male and female volunteers aged 65+, Goodwin *et al.* found that 17% drank more than 30 g alcohol/day on average[22]. In the EPESE, the percentage of persons who drank two or more

ounces of absolute alcohol/day was 8.4% in East Boston, 6.6% in New Haven, 5.4% in Iowa, and 7.2% in North Carolina[25,26].

The prevalence of heavy drinking in clinical samples is similar. Adams *et al.* screened 5065 patients aged 60+ seen in primary care and found 15% of the men and 12% of the women regularly drank in excess of recommended limits; 9% of the men and 2% of the women reported regularly consuming more than 21 drinks per week[33]. Bridgewater *et al.* reported that the prevalence of heavy drinking was 27% in men and 9% in women in their sample of 101 patients from general practice[27]. In their Liverpool study, Saunders *et al.* found a total of 6.1% of the men and 2.4% of the year 3 subjects regularly exceeded safe consumption limits. These figures translate into 19.5% of the men and 19.6% of the women being regular drinkers who were exceeding sensible limits. They observed a decline with age in the proportion of subjects who were regular drinkers[29]. Bristow and Clare interviewed 650 medical and geriatric admissions over 65 and found 9% of the men but few (0%) of the females drank in excess of recommended safety limits. Another 10% had cut down, primarily because of medical reasons. Compared to the non-drinkers and light drinkers, the heavy drinkers were more likely to smoke, not to be married, and to have some impairment of mobility[34]. Iliffe *et al.* found 3.6% of the men in their sample and 3.2% of the women admitted consuming more than 21 and 14 units of alcohol per week, amounts in excess of recommended safe limits for males and females. Neither drinking status nor total weekly alcohol consumption was associated with age, cognitive impairment, depression, falls or inpatient or outpatient care[28].

Although the overall prevalence is low, heavy drinking among older adults is of much concern, with perhaps as much as 20% of users drinking in excess of recommended limits.

IDENTIFICATION OF PROBLEM DRINKING IN THE ELDERLY

Physicians may have difficulty recognizing alcoholism in elderly subjects. First, screening instruments used in younger populations may not be reliable for older adults. Adams *et al.* compared responses to a beverage-specific self-administered questionnaire about the quantity and frequency of alcohol use and episodes of binge drinking to the widely used CAGE questionnaire (**C**ut down, **A**nnoyed by criticism, **G**uilty about drinking, **E**ye-opener drinks)[35] in 5065 primary care patients aged 60+ and found the CAGE performed poorly in detecting heavy or binge drinkers[33]. Lutrell *et al.* similarly concluded the sensitivity of standardized screening instruments was low in patients aged 65+ admitted as emergencies[36]. In addition, many of these screening instruments inquire about frequency and quantity of alcohol use. Many elderly may drink daily but in smaller amounts. These small quantities, however, may cause problems because of interactions with medications and chronic illness[4].

Second, criteria for alcoholism often include problems with social and/or occupational functioning. However, many older adults are less likely to be married or employed, and therefore less likely to report marital or job problems. Older drinkers may be more likely to maintain a "low profile" and not cause public disturbances resulting in legal problems[5].

Finally, physicians may fail to diagnose alcoholism in the elderly, perhaps because they often fail to obtain alcohol histories[37] or because they confuse perceived symptoms of aging with symptoms of alcoholism[5]. Curtis *et al.* screened all new admissions to the medical service at the Johns Hopkins Hospital for alcoholism using the CAGE[35] and the Short Michigan Alcohol Screening Test (SMAST)[38]. The prevalence of alcoholism was 27% in patients under age 60 and 21% in patients 60+. These age differences were not significant. However, 60% of screen-positive younger patients were identified as having alcoholism by their house officers, compared to only 37% of those aged 60+. Elderly patients with alcoholism were less likely to be diagnosed if they were White, female or had completed high school[39].

In a similar study, Adams *et al.* screened patients aged 65+ who came to the emergency department for alcoholism. Using their criteria of either CAGE-positive or self-reported drinking problem and alcohol use within the past year, they found the current prevalence of alcohol abuse was 14%, with a high prevalence (22%) among those presenting with gastrointestinal problems. Physicians, however, detected only 21% of current alcohol abusers[40]. In a study conducted in The Netherlands, scores on the Dutch version of the Munich Alcoholism Test[41] and medical records were obtained from 132 patients aged 65+ staying at University Hospital Leiden. Two-thirds of the alcoholic patients were recognized by the attending physician[30]. Finally, medical staff identified only 33 of 99 problem drinkers among inpatients aged 65+ in three hospitals in New South Wales[42].

These studies consistently show that older problem drinkers may be more difficult to identify as a result of poor screening instruments, failure of clinicians to consider problem drinking as a possible contributing diagnosis, and difficulty in separating problems caused by alcohol from those caused by other diseases.

FACTORS ASSOCIATED WITH ALCOHOL USE IN THE ELDERLY

Among the elderly, alcohol use has been shown to be associated with male gender[17,22,31–33,43], higher income[22], more education[22,33], lower socioeconomic status[32], being married[33] and current or former smoking[32–34]. Other studies have found alcohol use associated with less education[31]. Goodwin *et al.* found no differences in social support between elderly drinkers and non-drinkers and no relationship between alcohol intake and emotional status[22].

Two factors often associated with alcoholism in late life are depression and impairments in cognitive functioning. Saunders *et al.*, using data from their Liverpool study, reported 44% of men 65 or older with a history of heavy drinking were given current psychiatric diagnoses, compared with 12% of the men without a history of heavy drinking. The most common diagnoses were depression and dementia. The association between drinking history and current psychiatric morbidity was not explained by current drinking habits[44]. Finlayson *et al.*[45] studied 216 patients aged 65+ admitted to the hospital for treatment of alcoholism. Patients with late-onset alcoholism (aged 60+) reported a higher frequency of life events associated with problem drinking compared to those with earlier onset. The most common co-morbid psychiatric disorders were tobacco dependence (67%), organic brain syndrome (25%), atypical or mixed organic brain syndrome (19%) and affective disorder (12%); 14% of the patients had a drug abuse or dependence problem, all using legally prescribed drugs[45]. Similarly, Speckens *et al.* found that alcoholics used more psychotropic drugs compared to non-alcoholics and suffered more often from organic brain disease[30].

Iliffe *et al.*, however, found among patients aged 75+ that current drinking was not related to age, depression or mental status score[28]. Goodwin *et al.* found that those elderly who consumed alcohol performed better on the cognitive functioning tests, but no relationship was found between past alcohol consumption and present cognitive performance. The authors concluded that alcohol may not impair cognitive functioning in the elderly[22]. In a study of adults aged 70–75 in Italy, self-reported alcohol consumption was associated with male gender, better mood, less cognitive and functional impairment, better health, not living alone and being married, while CAGE-positive alcoholism

was associated with male gender, poorer cognitive function and income dissatisfaction. The groups did not overlap much, suggesting some positive aspects of alcohol use, and that self-reported consumption (they used the top 10% of quantity) may not necessarily be associated with alcoholism[46].

Mangion *et al.* found that men aged 65+ classified as alcohol abusers were more independently mobile than those not abusing alcohol, suggesting greater physical fitness[19]. Bristow and Clare, however, found that in an elderly inpatient sample, drinking in excess was associated with impairment in mobility[34].

Mirand and Welte studied the relationship between health-orientated lifestyle and heavy drinking among the elderly in Erie County, New York, and reported that the prevalence of heavy drinking was 6%. Heavy drinking was positively associated with being male, having suburban residency and currently smoking, and negatively associated with SES, rural residency and degree of health orientation. Age and level of active lifestyle were not related to drinking[32].

Molgaard *et al.* found racial differences among 65+ subjects in drinking level, both before and after age 40. Among Whites, 73.8% reported drinking after age 40, compared to 48.6% of Blacks and 44.3% of Mexican-Americans. A higher proportion of Whites than Blacks or Mexican-Americans reported more minimal drinking before and after age 40. However, there were no statistically significant differences for severe drinking among the groups[47].

ONSET OF PROBLEM DRINKING IN THE ELDERLY

Recent research has focused on the age-of-onset among elderly problem drinkers. Specifically, in several studies two groups have emerged. First, there are elderly who have had problems with alcohol most of their adult life and have survived to old age, generally referred to as "early-onset problem drinkers". There are also elderly who may or may not have consumed alcohol earlier in their lives, but who do not become problem drinkers until later in their adult life. This group is generally referred to as late-onset problem drinkers and the incidence of problem drinking has been hypothesized to be a result of a stressor.

Atkinson *et al.* studied the age of onset among 132 60+ men admitted into an outpatient treatment program and found onset after age 60 in 15% of the sample and in 29% of the sample aged 65+. Later-onset alcohol problems were milder and associated with greater psychological stability. Treatment variables were better predictors of treatment outcome than age of onset[48].

Brennen and Moos reported that late middle-aged problem drinkers reported more negative life events, chronic stressors, and social resource deficits than did non-problem drinkers[49]. However, in their same population, Brennen and Moos[50] studied men and women aged 55–65 and compared age-related loss events, overall negative life events and chronic stressors reported by late-onset, early-onset and non-problem drinkers. Late-onset problem drinkers consumed less alcohol than early-onset ones, reported fewer alcohol-related problems, functioned better, and had fewer stressors than early-onset drinkers. They did not find evidence for an association between age-related loss events and the onset of late-life drinking patterns. Similarly, Barnes found that neither widowhood nor retirement was related to heavy drinking. Heavy drinking was twice as prevalent among those subjects aged 60+ who were employed compared to unemployed[14].

Brennen *et al.*[51] found gender differences among late-middle-aged and older problem drinkers. Specifically, women with drinking problems consumed less alcohol, had fewer drinking problems, and reported more recent onset of drinking problems than did male problem drinkers. The female problem drinkers also used more psychoactive medications, were more depressed and were less likely to seek treatment. Osterling and Berglund studied gender differences in first-time admitted alcoholics aged 60+ to a treatment center in Sweden and found that age of onset of problem drinking occurred significantly later in females compared to males. During the period 1988–1992, sex ratios indicated a significant convergence of female patients compared with a decade earlier. The authors make it clear that it is not known whether this represents an increase in problem drinking in elderly females, or whether females feel more free to seek treatment than a decade earlier[52]. Hurt *et al.*[53] studied 216 patients aged 65+ admitted to an alcoholism treatment program. Early-onset alcoholism was present in 59% of the men and 51% of the women, while late-onset alcoholism was present in 39% of the men and 46% of the women (time of onset was not available for 2%). Few differences were noted between the two groups[53].

Moos *et al.*[54] followed their cohort of problem drinkers aged 55–65 for 1 year. Remitted problem drinkers were those who did not experience any problems in the 1 year follow-up period. At baseline, the to-be-remitted problem drinkers consumed less alcohol, reported fewer drinking problems, had friends who approved less of their drinking, and were likely to seek help from mental health practitioners. In addition, late-onset problem drinkers were more likely to remit over the 1 year period.

OUTCOMES ASSOCIATED WITH PROBLEM DRINKING IN THE ELDERLY

Some medical disorders have been found to be more prevalent in elderly with a history of alcohol use or current use. Hurt *et al.*[53] described 216 elderly patients aged 65+ treated for alcoholism in an inpatient treatment program. The frequency of serious medical disorders among this group was higher than what would be expected for the overall population aged 65+. Hypertension was less frequent among these patients, while alcoholic liver disease, chronic obstructive pulmonary disease, peptic ulcer disease and psoriasis were more prevalent among the alcoholic group. The frequencies of ischemic heart disease, cerebrovascular disease and diabetes mellitus were about the same as would be found in the general elderly population[53]. Bristow and Clare found, in their inpatient sample, that excess drinking was associated with more non-malignant respiratory disease and less ischemic heart disease[34].

Increased hospitalizations have also been linked with alcohol use in the elderly. Callahan and Tierney reported from their sample of patients aged 60+ that patients with alcoholism were more likely to be hospitalized (21.5% vs. 16.9%) ($p = 0.02$) within the year following the interview, compared to those without alcoholism[31]. Using 1989 hospital claims data, the prevalence of alcohol-related hospitalizations among people aged 65+ in the USA was 54.7 per 10 000 population for men and 14.8 per 10 000 for women, a proportion of hospitalizations among the elderly similar to that seen for myocardial infarction[55].

Alcoholism has also been linked with mortality in the elderly. Callahan and Tierney found in their sample of elderly patients that those with alcoholism were more likely to die within 2 years than those without evidence of alcoholism, 10.6% compared to 6.3% ($p = 0.001$), controlling for age, gender, race, education and smoking history[31]. In their study of inpatients treated for alcoholism, Hurt *et al.* followed 60 of their patients for an average of 5.2 years (range 2–11 years). A total of 32% of the alcoholic patients had died by follow-up. Of those who died, 47% of the deaths could be attributed to the patient's alcoholism[53]. Colsher and Wallace, using data from the Iowa 65+ Rural Health Study, found that 10.4% of the men had self-reported histories of having been previously heavier drinkers. Three-year mortality was higher among this group, compared to those men without a

history of heavy drinking[56]. Mellstrom *et al.* examined a cohort of 468 70-year-old Swedish men in 1971–1972, and reinterviewed them 5 years post-baseline (1976–1977) ($n = 342$) when they were 75 years old. In addition, they interviewed a control group of 70-year-old men in 1976–1977. Registration at the Temperance Board (recidivists) was used to measure previous alcohol abuse or large-scale consumption. Morbidity from diabetes and chronic bronchitis was higher in the recidivists, as was the overall 5 year mortality rate. Impaired functioning and a high consumption of institutional care were also more frequent among the recidivists[57].

Other researchers have also found impairments in functioning in those elderly with a history of alcohol use. Colsher and Wallace found that men with a history of heavy drinking had more illness, poorer self-perceived health, more physician visits, more depressive symptoms, lower levels of life satisfaction and smaller social networks compared to non-heavy drinkers and non-drinkers. The authors concluded that a history of heavy drinking was predictive of impairments in physical, psychological and social health and functioning among elderly men[56].

Some studies have found a protective effect of moderate alcohol use in the elderly. Scherr *et al.*, using the EPESE data from three sites, found that low to moderate alcohol consumption was associated with lowered 5 year total mortality as well as cardiovascular mortality in two of the sites, East Boston and New Haven. In Iowa, there were no differences in mortality by alcohol consumption. There was no association with cancer mortality found at any of the three sites. Patients with a baseline history of heart attack, stroke or cancer were excluded from their analyses[58]. LaCroix *et al.* found, by following three of the EPESE cohorts of elderly aged 65+ for 4 years, that risk of losing mobility, defined as the ability to climb up and down stairs and walk a half a mile, was associated with not consuming alcohol, compared with small to moderate amounts of alcohol consumption[59]. Galanis *et al.* recently conducted a longitudinal study of drinking and cognitive performance in elderly Japanese-American men and found lower scores on cognitive functioning tests in non-drinkers and heavy drinkers (more than 60 ounces of alcohol/month). Compared with non-drinkers, the risk of a lower score (more errors) on a cognitive functioning test was lowered by 22–40% among men who consumed 1–60 ounces of alcohol/month[60].

Finally, in a sample of 216 inpatients treated for alcoholism, the treatment outcome was favorable (i.e. the patient was either abstinent since treatment or abstinent with three or fewer minor slips) for 28% of the cohort of 60 patients, showing that the elderly alcoholic can be successfully treated[53].

SUMMARY

In summary, alcohol use, including drinking in excess, among older adults is prevalent, particularly among males. Because of interactions with chronic disease and use of prescribed medications, the use of alcohol among elderly individuals is an important health concern. Based on current use, the prevalence of alcohol use in future generations may be even higher. Screening and questioning for alcohol problems should be routine, since effective treatments are available. Drinking within recommended guidelines could potentially affect the proportion of alcohol-related illness, hospitalizations and mortality seen in the population.

Drug Misuse in the Elderly

Paul Bown, A. H. Ghodse and M. T. Abou-Saleh
St George's Hospital Medical School, London, UK

Substance misuse occurs mainly in young adults, with most of research focusing on this group. However, increasing age brings with it multiple pathologies and polypharmacy, with the attendant risks of dependence upon medication. There is evidence to support a growing trend to increased alcohol consumption in the over-65s, especially among women, while a generation of lifetime drug users are now entering old age[1]. The need for awareness of the possibility of the existence of such a hidden disorder has never been greater in this age group. The Persian physician Avicenna described four ages of man: an age of growth, an age of prime, an age of decline and an age of decrepit old age[2]. Those aged 65+ will include individuals in any of the latter three ages. Most research in the field has examined substance misuse by those in the declining stage.

USE, ABUSE AND HARMFUL USE

When considering drug use among the elderly it is helpful to consider substances of misuse in three broad categories: medications, both prescribed and non-prescribed; socially sanctioned psychoactive substances; and illicit substances. Religious, cultural and legal differences result in the same substances, e.g. alcohol or cannabis, being differently categorized around the world. For example, alcohol may fall within each of the three categories[3]. Some of the consequences of drug misuse are determined by the status of the drug rather than the physical effects of the drug. Difficulties in obtaining a drug supply and financing that use may account for as much harm as the physical effects of the drugs themselves in younger adults. Among the elderly, drugs from the medicines category are over-represented in cases of misuse when compared to other age groups. This reflects the increased access to medicines among this group, allied to the physical and social barriers that make accessing other drugs harder for this group.

At an intuitive level the clinician may balk at categorizing patients with poor compliance with misusers of non-therapeutic drugs. The aetiology, social perception and treatment approaches of the two groups differ markedly. This chapter will focus on drug misusers who display "harmful use". This is defined as:

> A pattern of psychoactive drug use that causes damage to health, either mental or physical[8].

This definition allows consideration of individuals suffering damage as a result of drug use, irrespective of the nature or the source of the drug of abuse. It excludes cases where omission of a psychoactive medication may be harmful, e.g. in cases of under-use of antidepressants.

Harmful use may be related to a single episode of drug misuse resulting in harm, such as a fall while intoxicated. More often it is a chronic condition associated with a dependence syndrome. "Dependence syndrome" describes the cluster of cognitive, behavioural and physical phenomena that are observed when use of a substance becomes a greater priority for the individual than other previously more valued activities. It is characterized by:

- A compulsion to take the substance.
- Difficulties in controlling the substance use in terms of timing and levels of use.
- Withdrawal symptoms on discontinuation of the substance, with relief of these symptoms on reinstatement of use.
- Tolerance or neuroadaptation, where increasing amounts of the substance are required to achieve effects previously possible at lower doses.
- Progressive neglect of alternative activities, due to prioritization of drug-related behaviour.
- Persistant use of the substance in spite of evidence of harmful consequences.

Presence of three or more of the above features simultaneously in the last year supports a definite diagnosis of dependence syndrome, using World Health Organization criteria[9].

PHARMACOKINETICS

Ageing is associated with a series of physiological changes that significantly alter the fraction of an ingested drug available for a psychoactive effect. Drug absorption shows little variation with age, despite changes in gastrointestinal motility and acidity, reduced absorption surface and slowed gastric emptying. However, once absorbed, the volume of distribution in an elderly subject is likely to have changed.

Ageing results in an increase in percentage body fat and a fall in total body water. Hydrophilic drugs, such as alcohol, are distributed in body water, such that with increasing age the volume of distribution falls and the peak concentration for a given dose may rise by 20%[10], resulting in lower levels of intake giving the same intoxicant effect. Conversely, lipophilic drugs, such as benzodiazepines and other psychotropics, that are stored in fatty tissue will remain in the body for longer but at lower peak concentrations. A fall in plasma albumin in old age results in increased bioavailability of protein-bound drugs, such as warfarin and diazepam.

Drug elimination occurs primarily through direct excretion or metabolism. Both routes are reduced in the elderly. Glomerular

filtration rates fall steadily in old age, leading to the accumulation of renally excreted drugs. This may be compounded by renal damage due to drug misuse, e.g. analgesic abuse[11]. Hepatic metabolism is impaired due to a loss of liver mass and a reduced blood flow, which may also be compounded by toxic drug effects, such as alcohol leading to fatty liver. The efficiency of microsomal oxidation also falls with age, leading to reduced drug excretion of hepatically metabolized drugs[12]. The combination of these effects may greatly alter pharmacokinetics in the elderly. For example, Klotz estimated the half-life of diazepam in the very elderly to be over 3 days, compared with 20 h in a younger subject[13].

Multiple drug use increases the difficulty of prediction of the behaviour pattern of an individual substance, due to competition for binding sites and metabolic pathways. Polypharmacy may have different effects, depending on whether it is acute or chronic. Alcohol will inhibit microsomal enzyme activity in acute use, while prolonged administration will induce the same enzymes. Hence, alcohol will acutely raise concentrations of benzodiazepines, while lowering them if used chronically[14].

Pharmacodynamics also alter in the elderly. Sensitivity to drugs, particularly those acting on the central nervous system, tends to increase, while drug receptor populations also change with increased age. The particular effect of the changes depends in part upon whether the receptor involved is facilitatory or inhibitory.

As a consequence of all these variables, the prediction of a drug's effects in the elderly, based on observation of its effects on younger adults, is foolhardy. Similarly rigid application of recommended "safe levels" of substance use, such as those issued by the Department of Health in the UK, may result in false reassurance to clinicians and patients with a consequent failure to identify cases of harmful use in the elderly.

CONCLUSION

The terms "old age" and "substance misuse" are both terms that have a wide range of meaning to different readers. The current literature is based primarily upon chronological age banding of individuals, as opposed to banding by overall health, possibly a more valid measure. Definitions of substance misuse are similarly varied. Often in transgenerational studies definitions of caseness are set at a level to prevent false-positive reports for younger adults. In older age groups, where less of a substance may have a greater effect, there is the possibility of missing cases if such standards are applied. The greater likelihood of drug interactions in the elderly should be considered when determining the dependency potential of any given drug or medication.

PREVALENCE AND CORRELATES

The elderly may display harmful use of any psychoactive substance. Misuse of alcohol, opioids, cannabinoids, sedatives, stimulants, hallucinogens and tobacco are all reported among the elderly. However, access to a potential substance of abuse is key to determining what an individual may misuse. Alcohol is obtainable with ease in most industrialized nations and is a socially acceptable and accessible psychoactive drug. Amongst the elderly, ill-health is common. Sedatives, hypnotics and analgesics are easily accessible through prescription and consequently, along with alcohol, are responsible for the majority of cases of harmful use. Over-the-counter medication is also easily obtained and may be misused. Illicit drugs are usually only available in potentially dangerous environments from individuals who may pose a significant risk to vulnerable older adults. Illicit drug use is not commonly observed in the elderly.

BENZODIAZEPINES

Benzodiazepines replaced barbiturates as the mainstay of pharmacological interventions in both anxiety and sleep disturbance. They maintain their relative dominance in this field despite the recent development of newer drugs with reportedly less addictive potential. Benzodiazepines accumulate more readily in the elderly due to changes in body composition, leading to a greater volume of distribution for lipophilic drugs. Chronic use may contribute to toxic effects, including cognitive impairment, poor attention and anterograde amnesia, cerebellar signs such as ataxia, dysarthria, tremor, impaired coordination and drowsiness[39]. Increased falls and hip fractures are associated with benzodiazepine use[40], whilst withdrawal may be accompanied by rebound insomnia, agitation, convulsions and an acute confusional state. If benzodiazepines are required then short-term use of low doses of short- or medium-acting drugs is advised. There is no "safe" period of use but tolerance and dependence levels increase with prolonged use[41].

Prevalence of Benzodiazepine Use

Establishing levels of benzodiazepine use is subject to the same difficulties as establishing alcohol use except where it is a prescription medication, when some idea of identity and demographic characteristics of the potential user should be available. In areas where benzodiazepines are available over the counter, the nature of users and misusers is harder to establish. National prescription audits can reflect trends in use but are unhelpful when considering particular population subgroups. Prescribing of benzodiazepines in England and Wales has fallen from 20.6 million prescriptions in 1987 to 13.9 million in 1996[42], a fall of 32%. In England in 1996, 55% of prescriptions for benzodiazepines were issued to patients over the age of 60. Many of these prescriptions were issued to long-term users. A recent community follow-up study of 5000 over-65s in Manchester[43] revealed that 10% were using benzodiazepines on first assessment and that of these some 70% were taking a benzodiazepine 2 years later. A further 4 year follow-up revealed that 69% of these were still on benzodiazepines. Patients entering the study on benzodiazepines had a 52% chance of taking benzodiazepines throughout the 4 year period. Women were twice as likely to be taking a benzodiazepine as men at any stage in the study. In the USA, a study found 6.3% of a large sample of over-65s used a hypnotic, one-third of these daily and nine-tenths for at least 1 year[44]. Five year follow-up found 46.6% still using hypnotics, but with a switch away from barbiturates and longer-acting benzodiazepines towards short-acting ones[45].

Use of benzodiazepines in institutional samples has traditionally been higher and associated with female gender, greater age, bereavement and poor health[46]. In the USA it has been shown that one-fifth of nursing-home residents were taking potentially addictive drugs on a daily basis. The medication in question is usually a benzodiazepine[47]. Studies from other countries reveal similarly high levels of benzodiazepine use among institutionalized older adults[48]. The level of morbidity among institutional residents is likely to be higher than community-dwelling elders. It is unclear whether this morbidity is sufficient to explain a doubling in levels of use of benzodiazepines in this group. While chronic pain may require treatment with dependence-inducing medication, there are few indications for long-term benzodiazepine use. It has been argued that the regular use of benzodiazepines in institutions is a form of behavioural control, used more for the benefit of staff and others than these users. In many cases, the individual may be incapable of giving valid consent to taking such medication. The use of medication in such circumstances may be

considered benzodiazepine misuse by some and as elder abuse by others[49].

Correlates

Psychiatric Morbidity

Significantly high rates of psychiatric disorder have been described among elderly benzodiazepine users[50]. Among elders using short-acting benzodiazepines as hypnotics, one-third reach caseness for depression, while a further one-third have a diagnosable anxiety disorder. Amongst users of anxiolytic benzodiazepines, half are depressed and one-fifth are anxious in spite of treatment. These results are not evidence of a causative relationship, although the most likely indications for initiation of such medication by a prescriber are likely to be presentation with such symptoms. As with alcohol misusers, one-third of elders requiring inpatient treatment for benzodiazepine misuse are of late onset, while two-thirds have graduated from misusing benzodiazepines or other drugs whilst younger[51]. The incidence of co-morbid alcohol abuse has not been consistently shown to be significantly greater among benzodiazepine misusers[51,52]. An all-age study found that DSM-III-R Axis I co-morbidity existed in all cases of a sample of benzodiazepine dependent users in Spain[53]. The commonest diagnoses were insomnia, anxiety disorders and affective disorders. Obsessive–compulsive, histrionic and dependent personality disorders were found in half the cases and physical problems in one-third of cases.

Gender and Age

Benzodiazepine use is over-represented among women of all ages. The likelihood of use of a benzodiazepine increases with age. There is little evidence that this gender divide narrows on reaching old age. Legislative approaches and prescribing guidelines have made some inroads into the over-representation of prescribing to the elderly[53]. Increasing public awareness of the side effects of benzodiazepines and an increase in advocacy services for the elderly are likely to have a similar effect.

Other Prescribed and Over-the-counter Medication

As indicated earlier, the elderly routinely receive a wide variety of medications, the majority of which may be misused. A quarter to half of the elderly experience chronic pain. In acute use the dependency potential of analgesics is believed to be around 0.1%. In chronic conditions the situation is somewhat different. Ten per cent of over-64s are on prescribed analgesics at any one time, with at least an equal number using over-the-counter medication. Edwards and Salib[54] found 3% of a community sample of over-65s to have been using mild opiate analgesics for a period of at least 1 year; 40% of this group were deemed to fulfil the criteria for dependence upon these drugs, with dependence levels as high as two-thirds among users of co-proxamol.

In addition to the dependence caused by these drugs, physical harm may also result, e.g. nephropathy may be caused by the use of paracetamol, salicylates and pyrazole derivatives, while renal impairment occurs with non-steroidal anti-inflammatory drug use[55]. Chronic nephropathy may also be caused by the excessive ingestion of analgesic mixtures combining two or more anti-pyretic analgesics, along with codeine or caffeine (both independently capable of causing addiction). Such acute and chronic effects are more likely amongst the elderly, where relative drug levels are higher and less biological reserve exists. Similar physical complications may arise from the misuse of other medications, the commonest being laxatives and cough mixtures.

ILLICIT DRUG MISUSE

Little is known about levels of illicit drug use among the over-65s, although the general perception is that it has been less of a problem than the misuse of prescribed medication. In the Epidemiological Catchment Area Study (ECA), only 0.1% of elders met the criteria for drug abuse for an illicit substance in the previous month[56]. Lifetime prevalence was 1.6% for over-65s. This may change as younger generations with a pattern of recreational drug use reach old age. In the UK, few cases of illicit drug use among the over-65s have found their way into the literature; one exception is a series of seven elderly reported to have initiated injecting heroin in later life. They attributed their behaviour to a combination of loneliness and depression[57]. In the USA, in a recent study of a Veterans' Administration old age psychiatry inpatient facility, 3% of the patients were found to have a primary drug misuse disorder involving prescribed medication, while 1% were addicted to illicit substances[58]. Also in the USA, attendance at methadone maintenance clinics by the elderly is reported to be rising, although over-60s still form 2% of those attending[59]. Similarly, a number of elders are reported to continue their use of cannabis into late life[47]. Anecdotal evidence also points to some individuals initiating the use of cannabis in later life in a search for its reputed therapeutic benefit in conditions such as disseminated sclerosis.

On balance, it appears that illicit drug use is less of a problem in the elderly than the abuse of legally sanctioned drugs. It remains to be seen whether individuals currently abusing illicit substances in younger age groups carry this behaviour over into old age. The nature of the subject has not lent itself to prospective studies as yet. One might expect greater levels of illicit drug use in future generations of older adults, although difficulties associated with obtaining a supply of such drugs with increasing infirmity are likely to account for some cessation in use. It is also tempting to speculate that those abusing illicit drugs as younger adults may switch to misusing prescribed medication in later life.

POLYSUBSTANCE MISUSE

The elderly have access to a variety of drugs of misuse. In many cases they may misuse one drug without misusing others. This is often the case with prescribed medication, where one medication is overused while compliance with the prescription is maintained for the others. Where non-prescribed substances become involved, the possibility of abuse of more than one substance is elevated. Finlayson[50] found 15% of over-65s requiring inpatient detoxification from alcohol were also dependent upon a second substance, usually a hypnotic, anxiolytic or analgesic.

The phenomenon of cross-tolerance must also be considered. Psychoactive substances may have a cumulative effect, due to either a shared outcome effect or to different drugs acting as interchangeable substitutes for one another (cross-tolerance). Cross-tolerance exists within each class of drug, such that the clinician should always consider the total benzodiazepine, barbiturate or opioid dose, using class-specific equivalence charts[60]. Cross-tolerance for some drugs may also occur outside of the class, most notably for alcohol, chlormethiazole and benzodiazepines. While this phenomenon is widely exploited for detoxification, failure to consider the possibility of its existence may lead to overlooking cases of dependence.

Conclusion

The abuse of alcohol and of prescribed medication remain the most prevalent substance misuse problems. There is little clear evidence of great changes in individuals' addictive behaviour patterns with increasing age. When one considers the prevalence of substance misuse among younger cohorts, it would appear that, as the population ages, not only will the absolute numbers of elderly with a substance misuse problem increase but the proportion of the elderly population with such a problem will increase too.

TREATMENT

Treatment of substance misuse is a multistage process involving the integrated use of physical, psychological and social interventions. These interventions should, where possible, run concurrently as opposed to consecutively and must be provided in a form that is acceptable to the individual and sensitive to the specific needs of the elderly. Amongst this client group, individuals rarely present complaining directly of a substance misuse disorder but may present with associated physical problems, or a problem may be detected during routine consultation with health professionals or carers.

The first step of treatment is the identification of cases. This requires clinical observation allied to sensitive yet persistent enquiry. The routine use of standardized screening tools may help to focus clinical impression more accurately. Once identified as potential candidates for treatment, the patient's attitude towards his/her substance misuse requires examination. Exploration of the risks and a discussion of potential avenues for change may help to establish or reinforce the motivation to change. Drugs that cause significant physical dependence may necessitate detoxification regimens, while co-morbid conditions such as depression that perpetuate the disorder need to be adequately treated. Social issues, such as housing and a social network that comprises mainly of substance misusers, may perpetuate the problem and need to be examined for opportunities to change. The individual requires psychological rehabilitation to address the issues that may have contributed to the uncontrolled use of substances and to provide future coping strategies to prevent a relapse into substance misuse. While these approaches apply to all substances of misuse, the majority of research has focused on alcohol misuse.

DETECTION

Self-presentation by elders may be limited by a number of factors[61]. Practical issues, such as accessibility of treatment centres to disabled individuals, large print information sources for the visually impaired and the availability of domiciliary treatment, are fundamental. Elders may not realize that they are ill, or may not realize that the medical profession identifies substance misuse as an illness and will offer help. Traditional forms of service promotion may fail to reach the elderly, while a service staffed by young professionals may seem intimidating or inappropriate for someone much older, particularly if his/her substance misuse is associated with a high degree of shame as is often the case in this group.

If self-presentation is unlikely, then the number of professional caregiver contacts that the elderly have provides a further opportunity for education of individuals about the problem and potential sources of help. This resource appears underdeveloped at present, with a need for better training for carers in identification of at-risk individuals and in appropriate actions once misusers are identified[62]. Currently, evidence suggests that carers are often unaware of sources of help and frequently are in collusion with alcohol misuse, citing reasons such as the elder "has not got long to live" or that "it's his only pleasure"[63]. Studies have found that many agencies providing care for the elderly have no written policy to guide their employees when encountering a client with an alcohol problem. Greenwood[64] argues that substance misusers, and the elderly in particular, suffer as the result of stigmatization, as their disorder is perceived as self-inflicted and with a poor outcome prognostically. This stigmatization may contribute to difficulties in communication and empathy on the part of some caregivers, including doctors. This stigma may be reflected in a clinician's reluctance to become involved by acknowledging a problem. For other carers, their own previous experiences with elderly substance misusers, both professional and personal, may lead to attempts to justify the behaviour, resulting in a similar loss of objectivity.

BENZODIAZEPINE USE DETECTION

Prevention and early recognition form the basis of management of benzodiazepine and other drug misuse among the elderly. Appropriate prescribing of sedatives for time-limited periods should be accompanied with vigilance for drug-seeking behaviours. Such behaviours include early requests for repeat prescriptions or requests for increased doses and should be regarded with suspicion. The elderly may also receive medication from multiple sources, particularly where they are under the care of prescribing hospital specialists as well as their primary prescribers. Careful exchange of clinical information is vital in such settings. For those abusing over-the-counter medication, chance presentation or the intervention of a pharmacist present the best hope of detection.

No screening tools have been validated to detect cases of elder benzodiazepine use. While urine screening provides a reliable means of establishing the presence or absence of drug metabolites, its clinical utility is limited by the unacceptability of the test to many who may be offended by the suggestion that they have a substance misuse problem. Second, urine screening is usually qualitative rather than quantitative. For those abusing a prescribed drug, the mere presence or absence of the drug is clinically uninformative. Individual variation in pharmacokinetics makes qualitative testing unreliable. With these considerations in mind, the need for dependence-inducing drug prescriptions should be regularly reviewed and co-morbid contributory conditions, such as depression, should be actively treated. Changes in legislation on prescribing practice may reduce the opportunity for drug misuse[71].

INITIATING TREATMENT

There are no published data about the level of uptake of offers of help once elders abusing substances are identified. Motivational interviewing and education as to the risks of alcohol use, along with the benefits of even a small reduction in levels of alcohol intake, may persuade some elders to change. Unfortunately, the pessimistic attitudes held by many professionals and carers towards the likelihood of successful resolution of the problem are frequently also held by the individual too. A fatalistic resignation to a life of substance misuse is often reported, particularly by long-term users, while more recent-onset users may express greater motivation for treatment[72].

Once long-term use of benzodiazepines is established, dose reduction can be difficult to achieve. Withdrawal insomnia and rebound anxiety make patient motivation difficult to achieve. Where abstinence is desired, a conversion to a medium-acting

benzodiazepine and a gradual reduction in dosage over the course of months is advisable. Rapid detoxification is associated with breakthrough withdrawal symptoms and may be complicated by convulsions. If a rapid withdrawal is necessary, it is best conducted in an inpatient setting if severe dependency is suspected. As with alcohol, the withdrawal period for the elderly is more likely to be complicated by confusion than in younger adults.

In cases where abstinence is not achievable or desirable, a minimization of dose and adoption of a non-daily pattern of use are reasonable targets. Psychological techniques, such as relaxation training and educative initiatives in the areas of sleep hygiene and correct medication use, may also prove valuable. Cormack[81] demonstrated that writing to benzodiazepine users in primary care urging them to reduce their medication use resulted in a fall in total use by one-third over the next 6 months.

Treatment of other forms of drug misuse in the elderly is under-researched. Anticipation of problems and safe prescribing remain paramount in treatment and prevention. Misuse of analgesics may require formal detoxification if opioids are involved or physical dependence has developed. More often the patient requires information to allow him/her to make an informed choice about drug use and an alternative form of treatment for his/her condition. Still less information is available on the treatment of illicit drug use in the elderly. At present there is no evidence to suggest that an approach other than that used for younger adults should be adopted, although adaptations of such treatments should involve lower doses of medication and the adoption of a less directly confrontational approach.

PSYCHOLOGICAL INTERVENTIONS

Once a patient is detoxified, rehabilitation is necessary to address the issues behind his/her substance use and to foster coping strategies for the future. Few studies have examined the particular needs of the elderly in a rehabilitation setting. Janik and Dunham report on comparative outcomes for over 3000 over-60-year-olds and younger entrants into alcohol treatment programmes[82]. Outcome measured in terms of alcohol intake, therapist assessment and alcohol problems after 6 months showed no differences between the groups.

Outcomes from programmes designed specifically with the elderly in mind may be more appropriate for consideration. Some success has been claimed for models encouraging the development of social networks with self-management skills[83]. Kofoed[84], in a small study, reported that retention in outpatient treatment of older adults was greater in an age-specific treatment group that focused on socialization and minimal confrontation (a mainstay of many programmes), compared with older patients in a mixed-age treatment group. At 1 year follow-up the effect was lost. Variations of the Alcoholics Anonymous 12-step model tailored to the needs of elders have been reported upon[85] in the USA, with varying degrees of success. Models low on confrontation, traditionally regarded as fundamental to overcoming denial on the part of the patient, appear to be supported by the work of Kashner[86], who found that 1 year follow-up of elders in a confrontational programme revealed half the levels of abstinence as compared with a group in a programme where self-esteem, tolerance and peer relationships were promoted. Behavioural approaches, including cue identification and avoidance, have also been reported to be of clinical benefit[83]. A programme focusing on cognitive techniques, such as cognitive restructuring, assertion training and self-monitoring of drinking, resulted in 75% of those completing the programme sticking to their treatment goals at 1 year follow-up. The evidence suggests that a range of therapeutic techniques may be beneficial for the elderly and that local provision may depend upon the skills available to the treating agency. It is suggested that even if an elder's only therapeutic programme is not available, a better therapeutic outcome may occur from a more homogeneous group, where the opportunity for identification and vicarious learning is enhanced.

The above studies all relate to the outcome of alcohol treatment programmes. Even less age-specific studies are available to guide the clinician in the provision of aftercare to the elderly non-alcoholic drug user. An avoidance of drugs that have a dependence potential is advisable if practical. Adequate rehabilitation and continuing support of the individual are indicated. This may be provided through generic old age psychiatry services or through specialist drug services, depending upon which service appears best able to cater for the specific needs of the user. The choice of service provider should reflect the lifestyle of the patient, as opposed to being a decision based solely on chronological as opposed to biological age. Further services may also be available in the form of mutual support groups similar to those available for alcohol. The adoption of a cognitively-based programme low on confrontation and designed to foster strong social support appears optimal, as shown in work in the field of alcohol.

Conclusion

Substance misuse and old age psychiatry have long been unpopular choices for specialization. Both fields are known for providing challenging patients with differing priorities to those of the clinician. Research in either field is hampered by the difficulty in obtaining reliable clinical data on conditions for which few empirical measures exist. The field of old age substance misuse has suffered to some extent in clinical practice, where patients do not fit neatly into either service and welcomed by neither.

It is, however, clear that there exists a significant morbidity due to drug use in the elderly. The problem may be iatrogenic and autogenic in origin. Increased life expectancy and the cohort effect of generations of recreational drug users reaching old age are likely to intensify the problem. Adequate research to identify at-risk individuals and the provision of appropriate and accessible treatment services for the elderly drug misuser remain one of the major challenges to health care providers at the start of the new millennium.

Benzodiazepine Use and Abuse in the Community: Liverpool Studies

Kenneth C. M. Wilson and Pat Mottram

St Catherine's Hospital, Birkenhead, UK

Benzodiazepine use in older people is associated with increased falls[1] and psychomotor changes, leading to the recommendation that they should rarely be prescribed[2]. Despite the fact that they may play an important role in the treatment of some psychiatric conditions[3], it is evident that they should be used with caution in this age group.

Recent epidemiological studies in Liverpool clearly demonstrate cause for concern. Between 1982 and 1983 we examined the prevalence of mental illness and the use of drugs in a random sample of 1070 community residents aged 65+[4]. A similar study was conducted on a larger age- and gender-stratified sample ($n=5222$) of the same age group between the years 1989 and 1991[5]. The Geriatric Mental State Examination was used in both studies. The instrument also collects data concerning prescribed and non-prescribed drug use over the month preceding the interview.

The results of the two studies have been compared in some detail[6]. The overall prevalence of benzodiazepine use was 12.8 (CI: 10.8–14.8) in 1982–1983 and 10.8 (CI: 9.9–11.6) 10 years later, indicating no significant change in drug use prevalence. Over the 3 years of the later study, 2.5% of non-users started taking benzodiazepines. Over two-thirds of all users were still taking benzodiazepines 3 years later. Analyses by mental state demonstrated that the largest proportion of people receiving benzodiazepines were depressed. People aged 80+ were three times more likely to be users than those aged 65–70. Both depression and anxiety were risk factors. Subsequent analyses of the data[7] examined the use of benzodiazepines in the context of depression. It is evident that nearly twice as many depressed older people were users of benzodiazepines than antidepressants. This may be explained by the increased emphasis on agitation, initial insomnia[8] and the relative under-reporting of depressed mood in older depressed people[9].

The findings of these studies should be viewed with some caution in view of the relatively long period between interviews in each study. It is self-evident that users may be intermittent in their use of benzodiazepines and other medications. However, the larger study incorporated questions concerning compliance. Data were available from 203/208 benzodiazepine users at their last interview. Of these, 89.6% stated that they were taking drugs as prescribed, 4.4% occasionally missed a dose and 5.4% often missed a dose. Only one stated that he/she had stopped taking the prescribed medication.

The findings of these studies imply that approximately 10% of older community residents are prescribed and taking benzodiazepines. Benzodiazepines are frequently prescribed to the very old and depressed, the majority of whom remain depressed for a significant period of time. Once commenced on benzodiazepines the majority take them for at least 3 years. There does not appear to be any change in prescribing habits across the interim period of 10 years.

Old Age and Learning Disability

Oyepeju Raji and Sheila Hollins
St George's Hospital Medical School, London, UK

The age structure of people with learning disabilities is changing and more are surviving into old age, indicating considerable achievements in health and social development.

Historically, there was little provision for the needs of older persons with learning disability. The reason for this was that such persons had a short lifespan and many died before reaching old age, for reasons such as inadequate medical treatment and the life-threatening complications associated with their condition. During recent years, the provision of formal care for adults with learning disabilities has changed from a largely institutional service to an increasingly community-based one. This has affected the collection of health statistics. Hospital populations provided the main source of data in the past. Although registers of need are a statutory requirement for children in the UK, there is no similar requirement for adults with disabilities. However, many local authorities do maintain learning disabilities registers, and include a wider range of service users than those who would previously have been long-stay hospital patients.

SOCIAL BACKGROUND

In the mid- to late 1800s, "mentally defectives" (including people with learning disabilities and those with mental illness) were kept away from society and were housed in asylums. One reason for the institutionalization of mildly learning-disabled people can be found in the social turmoil of the early 1900s. Young adults were placed in institutions to curb their sexuality, as it was thought that their offspring would have intellectual limitations and would themselves have low-IQ children, and that eventually the national IQ would fall. After the menopause, many of the women were allowed out on licence, working as ladies' maids, for example, and returning to the asylum when the problem of old age meant they were of no further use. Many were of normal intelligence, brought into institutions because of adverse social circumstances and detained there. After World War II, life expectancy began to improve within the institutions with better medical care and more positive lifestyles[2,3]. Mildly disabled older adults were highly valued as a substantial work force in the institution.

In 1959, a review of the Mental Health Act allowed patients an informal status and many became voluntary patients and discharged themselves, made their way into the world and were lost to helping agencies and statistics. Others stayed on in institutions, probably because of infirmity or institutionalization. Many of these will have been discharged as elderly individuals in the wave of community care in the 1980s, promoted by the philosophy of normalization and governmental encouragement. Wolf and Wright[3] found that younger, more able people were more readily discharged into the community and the older and more disabled population remained in institutions.

CAUSES OF DEATH

People with learning disabilities are living longer overall but the level of disability is correlated with longevity and this association is more marked in the earlier years. Improved standards of care, higher expectations and more positive attitudes to treatment for serious illness have contributed to increasing longevity. Prolonged survival is now the norm, even for the most severely disabled children. In people with Down's syndrome, for example, heart disease is now treated surgically if indicated and overall medical care is much improved. The overall increased longevity means that disorders such as dementia and cancer have become more prevalent. There is a tendency for profoundly learning-disabled people to be more seriously physically disabled and to have more health problems. Even with better care, the life expectancy of profoundly and multiply disabled people is still reduced. The mortality rate for people with learning disabilities is higher compared with the general population. Carter and Jancar[4,5] studied a hospital population and found marked changes in the causes of death over a 50 year period. Prior to 1955, tuberculosis was a major cause of death, and after 1955 non-tubercular respiratory infection accounted for 46% of all deaths examined. Other identified causes were myocardial infarction, cerebrovascular accidents, pulmonary embolism and status epilepticus, which accounted for 15%. Epilepsy is both more prevalent and more likely to occur in a poorly controlled form with significantly increased mortality[2]. Hollins *et al.*[6] reported that death certificates were not a reliable source of data about cause of death and that learning disabilities were rarely mentioned, with respiratory disease being the major cause of death, suggesting a failure to recognize underlying medical conditions. Those with mild disabilities have lifespans close to those of the general population, dying from cardiovascular, neoplastic and terminal infections, similar to those of elderly people of originally normal intelligence[7].

FREQUENCY OF DEMENTIA IN PEOPLE WITH LEARNING DISABILITY

Epidemiological studies, whether cross-sectional or longitudinal, are often difficult to do. The assessment of the premorbid state is affected by limited educational opportunities, social deprivation and the low expectations of many people with learning disabilities. The true intellectual functioning of the person with a learning

disability at baseline is often difficult to measure[1]. Studies suggest that dementia is about as common in the learning-disabled population as in the general population and has the same range of clinical phenomena, provided that each patient's unique intellectual baseline is allowed for[8]. Cooper[9] surveyed a population of elderly people with learning disabilities and found that 22% had dementia; however, the small number precluded analysis of subtypes. An earlier survey by Reid *et al.*[15] found a prevalence of 13.6%. Tait[10] found a prevalence of dementia similar to that in the general population.

THE MEDICAL CONTRIBUTION TO THE DIAGNOSIS OF DEMENTIA

Dementia can only be diagnosed after a careful history is taken and an examination made, the premorbid and presenting personalities assessed and other reasons for deterioration excluded. Long-standing visual and hearing problems are common in people with learning disabilities and may only be discovered as sensory deficits increase and further affect functioning[11]. Hypothyroidism, deterioration caused by inappropriate medication, communication disorders and psychiatric illness, both organic and functional, may all cause pseudodementia. Depression is often precipitated by loss of caregivers or familiar environments and may present, in addition, as behavioural and personality change. Symptoms such as incontinence may be related to the inappropriate architecture of the residence or to shortage of staff.

A detailed clinical examination will highlight dental and chiropody needs, general medical disorders and complications of long-standing disability. Consideration can be given to the need for aids and appliances to minimize the deficits and ease the burden for carers. People with learning disabilities rarely have access to health education or health promotion, so that screening for anaemia, hypertension, glaucoma or carcinoma of breast or cervix will hardly ever have been done.

The examination of someone with learning disabilities who may have superimposed dementia may therefore offer the opportunity to put right some of the deficiencies of older-style services, identify current social dilemmas, diagnose dementia in the context of long-standing deficits and consider, with the caregivers and the multidisciplinary team, how needs can be met[12].

Thorough assessment will provide information on the following:

1. The developmental intellectual disability.
2. Other long-standing disabilities and comorbid conditions.
3. Long-standing psychiatric illness and behaviour disorder.
4. Illness and disability superimposed and due to ageing.
5. Psychiatric illness associated with old age.
6. Dementia, if present.
7. The skills and needs of the person.
8. Recent life experiences.
9. The patient's wishes and those of the caregiver for residential and social care.

DEMENTIA AND DOWN'S SYNDROME

The association between ageing in adults with Down's syndrome and the development of dementia attracts interest from both researchers and clinicians. There is now a substantial literature on the genetic link between Down's syndrome and Alzheimer's disease. Several studies, using a variety of diagnostic criteria, have reported increasing age-specific prevalence rates for Alzheimer's disease in people with Down's syndrome. However, whilst the prevalence rates vary across studies, in no study has the rate reached 100%, which might be expected given the neuropathological data[13]. Dementia is often accompanied by epilepsy, loss of skills (which perhaps were not well developed in the first place) and transient behaviour problems, together with personality changes.

Families who have cared for their relative with Down's syndrome to the point where they develop dementia need support, information and the chance to talk to someone who understands the natural history of Alzheimer's disease. They may feel guilty and confused. An understanding of their confusion is required, and support is needed as they accept the diagnosis of dementia and its inevitable outcome. They may need to consider changes to their lifestyle and to look to the wider network for longer-term care and support.

WHAT OF SERVICES?

One of the most challenging ways to think about service development is through the proper consideration of the philosophy of normalization, which states that services that are highly valued and normative should be used by those who are at risk of being devalued. The difficulty is that both "the elderly" and "people with learning disabilities" are potentially devalued groups; both services tend to be underfunded and considered to be bottomless pits of needs.

The major debate is whether to use the services the rest of the population use, i.e. the geriatric or psychogeriatric services, to continue with learning disability services (improved as necessary), or to develop something new. Probably the best solution is to consider services for each individual, facilitating access to what is available and campaigning for what is not.

In England, national policy requires local authorities to offer person-centred planning to all people with learning disabilities. People living at home with elderly family carers are a priority group for receiving services and supports based on what is important for them as individuals and for receiving a regularly updated health action plan[16].

REHABILITATION INTO THE COMMUNITY

The closure of long-stay mental handicap hospitals in the UK has created new social and medical dilemmas[10]. Some people have been in hospital for many years, and moving into the community presents many difficulties, with geriatric needs superseding developmental disabilities. Some hospitals have remained to accommodate this small group, but many hospitals have closed completely and people moved to community residential provision. Many elderly people with learning disabilities have their only network of friends on the campus of the hospital, and it is important to try and maintain this. They are usually out of touch with relatives and a return to the county or borough of origin is not always meaningful or in their best interest. With careful introduction, these people may usually be accommodated in community services and may be far more competent than typical geriatric patients[14]. Because their life experience is so different, it may be better to care for them in an establishment able to take several residents from the same hospital.

CARE IN THE FAMILY HOME

The elderly person with learning disability may be cared for by an ageing parent with a similar dependency level. The fragile world of a person with learning disability has often been prematurely

closed because of the declining abilities of the caregiver. With the death of remaining carers, the experience of multiple loss may precipitate depression as part of the bereavement response[17]. A small group home may then provide a substitute for the family home. With foresight and planning, some people may stay in their own home, with up to 24 hours support if needed.

THE PERSON WITH MULTIPLE DISABILITIES

Learning disability is known to be associated with an increased prevalence of coexisting diagnoses that also affect life expectancy, with the result that those with multiple disabilities and superimposed problems of old age are few in number. There are challenges in management which may require a combination of learning disability, psychiatric and geriatric expertise. Some hospitals have developed special units to accommodate this small group, but new services are community-based and provide a multispecialty and multidisciplinary format. Private and voluntary agencies have often led the way.

DAY CARE

Accommodation and care varying from minimal to total are only part of the needs to be met. Daily activities and social contacts will need to be provided, and this may be difficult if the person has relocated in an area where he/she is not known. Because of shortage of places in social education centres (the core provision for adults with learning disability in the community), adults with learning disabilities usually retire by 65 years and then have only the occasional part-time arrangement in day centres for the elderly, clubs, adult education institutes and religious activities. As the number of elderly people with learning disabilities in the community increases, person-centred approaches to planning individual arrangements will be more important.

COMMUNITY TEAMS

Most areas in the UK have multidisciplinary community teams for people with learning disabilities and the trend is for these specialist staff to facilitate access to assessment and management within mainstream geriatric and psychogeriatric services. The opportunities of working together are great, thereby ensuring that dividing lines in health care do not detract from whole-person medicine.

TERMINAL CARE

Elderly people with learning disabilities may die at home, in oncology or general medical wards or in a hospice. The combined community services may be needed and include the terminal care team. Chaplains, moving from long-stay hospitals into ecumenical teams in the community, may be called to minister, together with community nurses and community team members, to ensure a dignified and good death.

CONCLUSION

The majority of elderly people with learning disability now live in the community and are more likely to outlive their parents and share the experience of becoming old with the rest of the population. This is an opportunity to meet their several needs successfully and not to repeat the errors of segregation that have littered learning disability services throughout the industrial world. There is need for more research at a clinical and planning level to underpin creative services, and up-to-date knowledge available for those who do the caring and for those who help the carers.

Elderly Offenders

Janet M. Parrott

Bracton Centre, Oxleas NHS Trust, UK

EXTENT AND PATTERN OF CRIMINAL BEHAVIOUR IN THE ELDERLY

Criminal behaviour is most common during youth and declines sharply with increasing age. Older people are responsible for only a small part of the total amount of recorded crime and it is likely that they also make a limited contribution to the "dark figure" of unrecorded offences. The lower proportion of males in the elderly population, their retired status and the absence of the risk-taking attitudes of youth may be of relevance. A review of the criminal statistics for England and Wales indicates that the elderly's share of most offence categories is less than 1% of the total for all ages. Shoplifting is the most common indictable offence to involve the elderly and this is the only offence category where older women make a significant contribution[1]. The elderly's share of sex offences (other than rape) is higher than for other indictable offences, varying between 5% and 9% of each category in England and Wales. Schichor[2] notes a similar 5% figure for the elderly's contribution to overall sex offences in the USA. Offences involving children are most common. In Craissati and McClurg's study of a consecutive series of 356 men from two London boroughs convicted of sex offences or released on parole (1993–2001), 22 men (6.1%) were aged 60 or over, 19 men were convicted of offences against children, two against adults and one of possession of prohibited material involving children[3,4]. The elderly contribute very little to the total number of those convicted of burglary, robbery and drug offences.

Violent behaviour in the elderly leading to conviction is extremely rare. Essex Police District recorded reports of violent incidents in only three people aged 65+ during a 14-month period[5]. In 1998–1999, 3.9% of homicides (19 cases) in England and Wales involved those aged 60+; six of these were convicted of Section 2 manslaughter (diminished responsibility), comprising 31.6% of the elderly group. In comparison, 6.8% of homicide cases where the perpetrators were under 60 resulted in a Section 2 manslaughter verdict, supporting the more prominent role of psychiatric disorder in the older offenders[1].

Kratcoski and Walker[6] studied 82 cases of homicide committed by those aged 60+ in the USA and concluded that elderly homicides were more likely to involve a spouse or other relative as victim than the non-elderly; 81% of the offenders were male, and 15% of the elderly offenders committed suicide, the victim being the wife in each instance.

Hucker and Ben Aron[7] compared 16 elderly violent offenders with a group of young violent offenders and with another group of non-violent elderly sex offenders, all selected by referral to a psychiatric clinic in a case note study; 69% of the elderly violent group were diagnosed as having either an organic brain syndrome or a functional psychosis, compared with only 19% of the non-violent elderly and none of the younger group. Paranoid symptoms were prominent in the elderly violent group, irrespective of diagnosis.

MENTAL ABNORMALITY AND OFFENDING IN OLD AGE

The most common associations of criminal behaviour in the elderly are alcohol abuse[8], homelessness and psychiatric illness[9]. In an early paper on this topic, Norwood East[10] suggested, on the basis of his clinical experience in prisons, that the possibility of psychiatric disorder should always be considered in those who offended for the first time in old age. Particular attention has also been drawn to first-offender shoplifters[11], although the contribution this disturbed group make to the whole is unknown.

In a study of 153 referrals aged 60+ to the community services branch of Essex police[12], 97 had been apprehended for shoplifting. The prevalence of psychiatric disorder in the 50 people interviewed was higher than in other community samples; 38% of those charged with shoplifting were identified as cases, with 9/11 cases belonging to AGECAT organic and depressive syndrome groups[13]. In a study of men remanded in custody, Taylor and Parrott[9] found that nearly 3% of men were aged 55+. Half of these men had active symptoms of psychiatric disorder and half some form of physical disorder—twice the rates of those under 55. The commonest psychiatric problems were alcoholism (27%) and major functional psychosis (37%). Less than a quarter of the over-65s had a permanent address, suggesting that homelessness was an important determinant of custodial remand. Twenty-four of 1062 restricted patients admitted to hospital in 1998 in England and Wales were aged 60+; nine of these patients had been convicted of homicide, six of other violent offences and two of sexual offences[14].

CLINICAL ASPECTS OF OFFENDING IN THE ELDERLY

Affective Disorder

Roth[15] noted that the rare violent acts committed by aged men often arise in a setting of depressive illness with suicidal ideation. Depressive homicide most often involves a man killing his wife. The killing is generally viewed by the patient as at least partly altruistic, on account of thoughts that she would be unable to cope without him, although a dynamic formulation may indicate unacknowledged hostility. It is common for the act to be followed

by suicide. Knight described several cases, noting that there is generally no history of previous violence or discord[16].

The disinhibition and irritability of mania may also lead to aggressive behaviour, although serious violence is uncommon. Both types of mood disorder may be associated with shoplifting, on account of poor concentration, diminished concern about social rules or associated dynamic factors. In relation to shoplifting, an emotional disturbance following a life crisis but falling short of depressive illness may form the background to the offence. It should also be borne in mind that the trauma of arrest itself in an elderly person with no previous symptoms may lead to psychiatric sequelae, including suicidal ideation.

Case History 1: Depressive Homicide

A 68-year-old man with previous episodes of depressive illness developed depressed mood and agitation over several weeks. There was no history of violence and he was known as a quiet kindly man. He became preoccupied with two themes, first that the water supply in his house was infected and had caused his wife's psoriasis, and second with guilt regarding a minor sexual misdemeanour that had occurred during his teens. His wife asked him to just try and do the shopping, something he found particularly difficult when depressed. He experienced the sudden thought that if he killed her, the action would have the dual benefit of releasing his wife from her misery and ensuring that he received a life sentence, a fitting punishment for the sexual misdemeanour. He strangled her and rang the police. He was bailed to hospital and later placed on probation, with a condition of psychiatric treatment.

Case History 2: Shoplifting and Depression

A 75-year-old retired plasterer with no previous convictions received the news that his son-in-law was having an affair. He himself had endured a stressful marriage for a lifetime. He became depressed in mood and overwhelmed by intrusive, angry thoughts towards his son-in-law. His sleep became disturbed and his powers of concentration diminished. While shopping he was observed to pick up a paint brush and slip it into his jacket. He then clambered over a barrier to leave the store. The shop refused to stop proceedings, but the Court dismissed the charge on hearing psychiatric evidence. The emotional crisis subsided with time and a period of supportive counselling.

Schizophrenia

The most common offence associated with schizophrenia in those that are homeless is shoplifting. However, both violent offences and arson may occur, on account of paranoid ideation.

Case History 3: Violence Associated with Paranoid Delusions

A 75-year-old man was arrested following his approaching a group in his local pub, grabbing one person by the neck and cutting his lower throat with a carving knife. The publican reported that the elderly man was a moderate drinker and that he had been expressing abnormal ideas over the previous year. He had had a partial pneumonectomy for lung cancer 3 years prior to the offence. At interview he said that neighbours watched him all the time, made derogatory remarks about him and had a laser machine which they used on his body. On the day of the offence, he said he had heard one of the group of men say "He stinks", and concluded that they were associated with those acting against him. He returned home for a knife and said later he only wished to frighten the victim. No evidence of recurrence of his lung cancer was found at that stage. Following treatment with antipsychotic medication, he no longer complained of abnormal experiences, although he retained some delusional ideas. He became relaxed and content in contrast to his agitated state prior to treatment and said that he had no desire to revenge himself on the people involved in the paranoid ideation. He pleaded guilty to wounding with intent and was placed on a hospital order under Section 37 of the Mental Health Act (1983), with restrictions on discharge under Section 41. There were no management problems, although he remained in hospital until his death with metastases 18 months later.

Dementia

Assaultative behaviour in dementia is not uncommon, although within a family or institutional setting the behaviour is unlikely to form the basis of a formal charge. Disinhibition, misinterpretation and the pressures of close living with others may be contributory factors. Petrie *et al.*[17] studied a series of 222 consecutive admissions to a psychogeriatric unit in the USA and noted that 139 had shown verbal aggression or violence, 18 incidents involving the use of knives or guns; 39 of these patients were suffering from senile dementia and the remainder from functional psychoses. Disinhibited sexual behaviour or fire-setting may also reflect the loss of cortical inhibiting factors in dementia.

Persistent theft from shops may be linked with absent-mindedness in the early stages of illness or with a more general deterioration in social behaviour at a later stage. Mendez described a case of persistent stealing in a 71-year-old man with dementia who constantly picked up small items with no explanation for his actions[18].

Alcoholism

In addition to alcohol-related offences, such as driving while intoxicated, problem drinking may be associated with theft, criminal damage, violent or sex offences. Many cases involve a variety of factors, e.g. about one-third of elderly homicide offenders in a series studying coroners' files had been drinking at the time of the killing[6].

ASSESSMENT OF THE ELDERLY OFFENDER

A careful assessment of mental and physical health and of the person's social circumstances and the quality of relationships within this is necessary. Particular note should be taken of the use of alcohol and of prescribed or proprietary medication. Where the charge is more serious, full details of the allegation should be obtained from witness statements and informants.

In assessing a defendant's fitness to plead, consideration is particularly given to the defendant's ability to understand the nature of the charge and the significance of his plea and to follow the process of the trial. In some cases, discontinuation of proceedings may be more appropriate.

THE ELDERLY WITHIN THE CRIMINAL JUSTICE SYSTEM

Appropriate assessment that would identify those offenders requiring social and psychiatric intervention is often lacking,

although there has been a greater emphasis on diversion from the criminal justice system in recent years. Cautioning is as common a disposal as conviction in England and Wales for all but the most serious crimes in those aged 60 +[5]. In addition, many shops have adopted policies of not reporting shoplifting in those of retirement age, preferring to ban persistent offenders from their premises. In the USA a number of schemes have been developed to deal with the older offender, both pre-trial and after sentencing[17].

In the Essex cohort of 153 elderly offenders studied by Needham-Bennett *et al.*[12], 97 (65%) were cautioned and in 42 (28%) there was no further action. The police, however, referred only half of those later identified as psychiatric cases to welfare agencies, suggesting that closer links between the police and community psychiatric teams for the elderly might facilitate the identification of unmet mental health needs at an early stage.

The elderly serving sentences comprise both those imprisoned for the first time in old age and those who have grown old in prison. About 1% of the prison population in the UK is aged 60 + and about 5% in the USA. The number of sentenced prisoners in the UK aged 60 + has increased in recent years, from 333 in 1988 to 1055 in 1998, although there has not been a similar increase in the elderly remand population[1]. A case history-based study in the USA of 25 new elderly offenders, most of whom were imprisoned for sex offences or homicide[19], drew attention to their initial reaction to imprisonment, often being characterized by family conflict, depression, suicidal thoughts and a fear of dying in prison[19]. The physical health of older prisoners is also important, with about half of older prisoners having a long-standing illness or disability[20]. The prison system makes scant provision for vulnerable groups and older prisoners may experience particular difficulties in adjustment on release.

Sleep and Ageing: Disorders and Management

Helen Chiu
Chinese University of Hong Kong, People's Republic of China

Sleep complaints are very common in the elderly, with up to 40% being affected by insomnia. Further, a disproportionately large number of prescriptions of sedative–hypnotics are given to elderly people. Sleep disturbances in the elderly may be the result of physiological changes with the ageing process, poor sleep hygiene, medical and psychiatric conditions (particularly depression) leading to secondary sleep disturbance, and primary sleep disorders[1].

A number of changes in sleep characteristics and architecture occurs with ageing. In general, the older person takes more time to fall asleep, has more awakenings and less efficient sleep, as well as more napping in the daytime. Moreover, the older person tends to go to bed early and rise early, reflecting a phase-advanced rhythm of the sleep–wake pattern. In addition, there is a decrease in slow wave sleep and rapid eye movement (REM) sleep but an increase in light sleep, i.e. stages 1 and 2 of NREM sleep[1–3].

Inadequate sleep hygiene includes poor sleep habits and engaging in sleep-incompatible behaviour[4]. Excessive time in bed, irregular hour of going to bed, lack of exercise, excessive caffeine intake, alcohol withdrawal and noisy environment are all factors that might influence sleep.

Numerous medical conditions can lead to sleep disturbances, especially when pain is a significant feature. In the elderly, dementia is a common cause of sleep disturbance. In Alzheimer's disease, there is a decrease in slow-wave sleep and REM sleep, with increased fragmentation of sleep. A disrupted sleep–wake cycle is frequently found. Agitation and confusion in the evening and at night (sundowning) may also occur in some patients[5].

As for primary sleep disorders, sleep apnoea, REM sleep behaviour disorder and periodic leg movement during sleep (PLMS) are the ones with increased prevalence in the elderly, and will be dealt with in this chapter.

SLEEP APNOEA

A period of apnoea is defined by a cessation of breathing for 10 s or more, whereas a hypopnoea period is a 50% reduction in the respiratory depth for 10 seconds or more. Sleep apnoea is characterized by recurrent episodes of apnoea and hypopnoea during sleep, and is usually associated with oxygen desaturation in the blood[6].

There are two main types of sleep apnoea, obstructive and central. Obstructive sleep apnoea is the more common form. Cardinal features are loud snoring and excessive daytime sleepiness. Associated features include headache, insomnia, apnoea observed during sleep, excessive movements during sleep, cognitive impairment, personality changes and enuresis. Physical problems include systemic hypertension, pulmonary hypertension and cor pulmonale[6], which might explain why sleep apnoea is associated with an increased mortality due to cardiovascular events.

The exact prevalence of sleep apnoea is unknown but it is estimated that about 2–4% of the general population meet minimal criteria for obstructive sleep apnoea[7]. Its frequency increases with age, reaching a maximum between 50 and 70 years of age, and there is a male predominance. In the elderly, prevalence rates of 26–73% have been reported in various studies[8]. This shows that disordered breathing is a common problem in the elderly. However, a major unresolved issue is whether sleep apnoea is a less pathological condition in the elderly. Studies in clinical populations have shown that disturbed respiration during sleep in the elderly has minimal association with mortality and morbidity, while epidemiologic studies in the elderly have suggested otherwise[2]. Pending further studies to clarify the issue, older people with symptomatic sleep apnoea probably should be treated in the same way as younger patients.

In the management of sleep apnoea, general measures include weight reduction and avoidance of alcohol and benzodiazepines before bedtime. In the majority of patients with sleep apnoea, continuous positive airway pressure (CPAP) during sleep is the treatment of choice. Surgical treatment may be indicated for patients with specific upper airway abnormality who have failed CPAP therapy or did not want CPAP for various reasons, such as frequent travelling[9].

REM SLEEP BEHAVIOUR DISORDER (RSBD)

This is a recently described parasomnia[10]. Presenting features are usually excessive motor activity during sleep, which may lead to repeated injuries to the patients or their bed-partners. Patients may talk or shout aloud in sleep, accompanied by vigorous limb movements, walking, falling out of bed, or carrying out various activities in their dreams. After awakening, patients may recall dreams that coincide with their motor activities. This suggests that the motor activity in sleep is a form of dream enactment. Some patients resort to various measures to protect themselves from injury, like tying themselves to the bed or putting a mattress on the floor. In addition, the nature of their dreams may change over the years, becoming very vivid and action-packed[11]. The diagnosis of RSBD should be considered in elderly people presenting with sleep-related injury or violence.

Principles and Practice of Geriatric Psychiatry, 2nd edn. Edited by J. R. M. Copeland, M. T. Abou-Saleh and D. G. Blazer

There are very few studies on the prevalence of RSBD. A study in the general population by telephone interview found that 0.5% had probable RSBD[12]. Another study on a community sample of elderly reported a rate of 0.4%[13]. RSBD tends to occur predominantly in the elderly, and males are more affected. In general, the awareness of this condition is low among the public as well as clinicians, and misdiagnosis is common.

RSBD occurs in transient or chronic form[11]. The transient form may be induced by drugs as well as alcohol withdrawal. The chronic form is either idiopathic or associated with neurological disorders in up to 50% of cases, such as dementia, Parkinson's disease, multiple system atrophy and vascular or neoplastic lesions of the central nervous system. In particular, there is a strong association with Parkinson's disease and dementia with Lewy bodies[14,15].

The exact aetiology and pathophysiology of RSBD is unclear. In normal people, there is generalized muscle paralysis during REM sleep, sparing only the diaphragm and extraocular muscles. In RSBD there is a disruption of this pattern and patients can thus move and act out their dreams[11].

Management of RSBD includes drug treatment with clonazepam, which is effective in up to 90% of cases, as well as safety measures to protect the patients from injuries[16].

PERIODIC LEG MOVEMENT IN SLEEP

Previously known as nocturnal myoclonus, PLMS consists of stereotyped, periodic jerky movements of the lower limbs, usually occurring in light sleep. Symptoms include leg jerks, insomnia, daytime sleepiness and sometimes cold feet[17]. PLMS is associated with restless legs syndrome (RLS), which is characterized by the presence of unpleasant sensation in the lower limbs occurring when the patient lies down in bed, frequently leading to insomnia. However, PLMS can occur independently of RLS.

PLMS may occur as an isolated finding, but has been observed in a number of pathological conditions, such as chronic myelopathies and peripheral neuropathies, uraemia and sleep apnoea[18].

PLMS is very common in the elderly; studies have reported rates up to 45%[17]. Nevertheless, the relationship of PLMS and insomnia is still a matter of debate. It has been suggested that PLMS may be coincidental with sleep–wake disorders, rather than being a cause of it; indeed, many elderly with PLMS are completely asymptomatic.

Mild cases of PLMS may not need any treatment. For more severe cases, options of drug treatment include benzodiazepines (particularly clonazepam), L-dopa, bromocriptine and opiates[18].

Rating Scale for Aggressive Behaviour in the Elderly

L. C. W. Lam

The Chinese University of Hong Kong, People's Republic of China

Aggressive behaviour is one of the commonest causes for psychogeriatric admissions. It is highly correlated with carers' distress and rejection, as well as a decision for long-term institutional care[1–2]. To rationally evaluate the effectiveness of intervention strategies for aggressive behaviour, it would be very important to identify suitable assessment tools. The Rating Scale for Aggressive Behavior in the Elderly (RAGE) is specifically designed for the assessment of this aspect of behavioural problems in psychogeriatric institutional settings[3].

The RAGE is a 21-item rating scale administered by trained professionals, usually the nursing staff in the setting. The items include different dimensions of aggression (verbal, agitation and physical aggression), with no pre-defined diagnostic specifications. Aggressive behaviour is defined in the RAGE as "an overt act, involving the delivery of noxious stimuli to another organism, object or self, which is clearly not accidental". The scale is observer-rated and the staff is requested to complete the questionnaire based on observation in the ward over a 3 day period.

Table 1. Items in the RAGE

Item	Ratings
Demanding	0–3
Shouted	0–3
Swore	0–3
Disobeyed ward rules	0–3
Uncooperative	0–3
Irritable	0–3
Sarcastic	0–3
Impatient	0–3
Threatened to harm	0–3
Antisocial acts	0–3
Pushed others	0–3
Destroyed property	0–3
Angry with self	0–3
Attempted to kick	0–3
Attempted to hit	0–3
Attempted to bite	0–3
Used object to hurt others	0–3
Self-inflicted injury	0–3
Injury to others	0–3
Sedation or restraint	0–3
Overall aggressiveness	0–3

Patel and Hope[1] reported that the RAGE demonstrated good psychometric properties, with satisfactory reliability and validity. Comparison of RAGE with two other commonly used scales for aggression, the Cohen–Mansfield Agitation Inventory and the Brief Agitation Inventory, revealed that the three scales all highly intercorrelated, with meaningful constructs[4].

Studies using RAGE to measure aggressive behaviour in institutional settings revealed that about half of the elderly in psychogeriatric wards had positive ratings in aggressive episodes over a 3 day observation period. It was found that elderly schizophrenic patients, when compared with the demented elderly, were more frequently rated as overall aggressive, albeit with the same total scores in the RAGE[5]. The scores on the RAGE were found to be higher in moderate degree of dementia, and were also reported to be associated with activity disturbance and the presence of psychotic features[6].

Sexual Disorders

J. M. Kellett

St George's Hospital Medical School, London, UK

THE CAUSE OF ERECTILE FAILURE

Although levels of free testosterone fall with age. this does not relate to levels of sexual activity[1,2], which correlate closely with age itself. Three hypotheses for the decline remain (although whether loss of interest leads to erectile failure or vice versa is in doubt); these are: (a) that increasing atheroma causes a failure of vasodilation sufficient to cause an erection; (b) that degenerative changes in the autonomic system are the cause; and (c) that levels of self-confidence decline with age, leading to psychogenic failure. Clinical impressions do not support the latter hypothesis, and a study of 28 men with erectile failure over age 65 compared to 25 aged-matched men who were potent showed no differences in their GHQ[3].

Feldman *et al.*[4] compared measures of health in 1290 males aged 40–70 in Massachusetts and found erectile failure to be increased with heart disease, diabetes, hypertension, depression and anger, and decreased by high-density cholesterol and by levels of dihydroepiandrosterone, a breakdown product of testosterone, but not by levels of testosterone itself. They did not measure neuronal ageing. Rowland *et al.*[5] found that penile sensitivity was related to erectile response. In our study[3] reported above, we found that only a measure of autonomic neuronal integrity (pilocarpine-induced sweating) distinguished the two groups fully. This might suggest that most elderly men with erectile failure would respond to corporeal vasodilators, which would be less effective if the cause was atheroma. The subject is well covered by Schiavi[6].

TREATMENT

Counselling allows the couple to express their fears and inhibitions, whilst the therapist can educate them about the normal changes of ageing. Elderly men, for example, often overestimate the importance of penetration, compared to petting, in the pleasure they give to their partner. Physical remedies are more widely used and include vacuum pumps[7], intracavernosal[8] and intraurethral[9] administration of alprostadil, oral sildenafil[10], which prolongs the action of cavernosal nitric oxide, and oxpentifylline for vasculogenic failure. Dopaminergic drugs can restore libido, if fear of prostatic cancer contraindicates testosterone. Disorders of female arousal are reduced by HRT and also respond to sildenafil[11].

Phenomenology of Wandering

A. Habib and G. T. Grossberg
St Louis University, MO, USA

With current increases in the elderly population, dementia and its related behavioral disturbances are receiving much more attention. Wandering is one of the common, often treatment-resistant behavioral concomitants of progressive dementia. Most research on wandering has focused on nursing home- or dementia clinic-based samples. In these samples, wandering occurs in up to 65% of patients at some point in the disease process[1–7].

DEFINITION AND PHENOMENOLOGY

There has been much debate about the appropriate definition of wandering, as well as its phenomenology. A major difficulty in wandering research has been the lack of a uniform definition and of reliable assessment instruments. Wandering was initially defined as "aimless movement"[8,9]. More recent definitions have viewed wandering not only as aimless, but also as having purposeful intent[10,11]. Wandering has further been classified, on the basis of phenomenology, as benign or problematic[8]. A benign wanderer is a patient who roams aimlessly and is easily redirectable, whereas a problem wanderer is one who is disruptive to family, staff or other residents and includes the individual who is resistant to redirection. Attempts have made to quantify wandering behavior into two broad categories, continuous and sporadic. "Continuous wanderers" are defined as ambulating more than 50% of their wakeful time, while "sporadic wanderers" move about for less than half of their wakeful time.

A common theme that is consistently supported in the literature is that wandering is primarily influenced by a continuity of behaviors from earlier premorbid times[12]. Recent research[13] has also focused on the relationship of premorbid personality and wandering. Overall, wandering is viewed as having a beneficial effect for the wanderer by fulfilling a particular need. De Leon *et al.*[18] showed that wanderers had poorer parietal lobe functioning than subjects with similar degrees of cognitive impairment. However, in a multisite, random sample of 163 ambulatory, cognitively impaired subjects, wanderers showed significantly greater impairment in basic skills (orientation, memory and concentration) and in the higher-order skills of language, abstract thinking, judgement and spatial skills[14]. In Monsour and Robb's[12] sample of wanderers, 36/44 subjects had dementia or Alzheimer's disease; eight had cerebral vascular accidents or arteriosclerosis. Although wanderers may have more cognitive decline, they often exhibit an intact social facade, which masks their deficits[15]. Snyder *et al.* also identifies that wanderers had a higher number of psychosocial needs than non-wanderers on the Human Development Inventory (HDI).

Table 115.1 Why patients wander

Trying to find "home"
Trying to find bathroom
Are hungry
Are in pain
Acute medical or environmental trigger, stress, or loss
Drug side effect or withdrawal
Are bored

Triggers of Wandering

Table 115.1 lists some common reasons why patients wander. They may be trying to find "home" or their room, whereas some are merely driven by the urge to void and are trying to find a bathroom. Some patients may be scavenging for food because they are hungry. Wandering behavior may be due to pain, e.g. arthritis or other painful medical states, which the patient cannot communicate. If the wandering behavior is of abrupt onset, one needs to ask if an acute stress or loss, whether a medical (e.g. an infection) or environmental (e.g. death of a roommate or family member) factor has triggered the wandering behavior. At times, wandering may be due to boredom.

TREATMENT

Table 115.2 highlights general treatment approaches to wandering behavior. The management of wandering behavior can be classified into three groups according to the potential etiology of the wandering behavior: (a) medical; (b) psychosocial; and (c) environmental.

The most important cause of wandering to exclude is an acute or chronic underlying medical problem, for example, an abrupt arrhythmia. Also, could the need to be on the move be a side effect of medications? Akathisia with neuroleptics or agitation with

Table 115.2 Treatment of wandering: general approaches

Eliminate physical/chemical restraints
Wander-safe indoor and outdoor areas
Eliminate distracting light and noise from environment
Use of electronic elopement prevention devices and patient identification bracelets
Proper staffing
Staff education and training
Philosophy of rehabilitation

fluoxetine are examples. Perhaps a withdrawal syndrome, such as from alcohol or benzodiazepines, may be implicated. Pain as a trigger for wandering always needs to be considered.

In the nursing home, proper staffing, appropriate staff training with regard to causes and management of wandering behavior, coupled with supervised structured activities, such as music therapy and simple crafts, are important. Use of planned activities and distraction techniques may be helpful.

One of the key elements in managing wandering behaviors is to provide an appropriate and safe environment where wandering behavior can be tolerated. This should ideally include specially designed indoor and outdoor roaming areas that lack safety hazards or distracting elements. Innovative ideas include a "reduced stimulation unit"[11,16] and a "wanderer's lounge program"[17]. It is vital that wandering behavior is not dealt with via the use of physical restraints or the heavy use of sedatives or tranquilizers. Patients often fight such measures, resulting in more significant problem behaviors.

A major concern for family or institutional caregivers is that the wandering patient may elope and come to physical harm, e.g. run into automobile traffic. The use of "Wander-Guard"-type devices on doors and a special identification bracelet, labeled "cognitively impaired—if lost, please call (phone number of facility)" may help.

CONCLUSIONS

Wandering exacts a heavy toll on family and professional caregivers. For the wanderer, issues of safety are of paramount concern. To ease the burden on caregivers, it is important to try to ascertain *why* the patient is wandering. This will usually give clues to appropriate management. Unfortunately, wandering patients usually cannot communicate why they are wandering because of their cognitive impairment. Consequently, caregivers need to place themselves in the patient's shoes to come up with the answers.

Problems of Assessing Psychiatric Symptoms and Illness in Different Cultures

Melanie Abas
University of Auckland, New Zealand

Increasingly, psychiatrists must have the skills to assess and deliver care for people from different cultures. Many areas can only be touched on here, and several of the references stem from the cross-cultural literature in younger adults. The context is very broad, covering industrialized countries with multicultural populations and less-industrialized countries. It is worth noting that, due to a range of barriers, many people from different cultures have, of course, very poor access to psychiatric assessment and care[1–4].

COMMUNICATION AND CULTURAL AWARENESS

While health staff often come from different cultures than their patients[5], they are usually working within at least a familiar framework and landscape. With someone from a very different culture, the ability to assess appearance, behaviour and symptoms will be limited. The practitioner must work harder to gather the information to make an accurate assessment and to develop rapport and trust. Awareness of one's lack of information of one's own cultural "encumbrances" and of potential strong feelings about each other's cultures is crucial[6]. Training and consultation with a wide circle of people from the relevant culture is needed. Ask the patient early on about his/her background and, for migrants, his/her place of origin and experience in the new setting. Listening, asking open questions, acknowledging family expectations and a willingness to discuss issues such as racism and social needs are all vital. Within reasonable professional boundaries, the psychiatrist should be willing to respond to some questions about him/herself. For example, with older Jamaican migrants, culture-specific care providers stressed that making "a connection" with the doctor would facilitate the assessment and acceptance of care[7]. Show sensitivity but do not neglect important areas on "cultural" grounds, such as alcohol intake in Muslims. Apparent persecutory ideas must be explored and may reflect an appropriate response to injustice.

Language barriers should be addressed through the employment of ethnically close bilingual workers, otherwise use a competent interpreting and advocacy service[8]. Using relatives or other staff to interpret should be limited to emergencies. Requiring patients to speak in their second language can distort the clinical picture[6]. Aspects of non-verbal communication may also differ, such as avoidance of direct eye-to-eye contact in some Asian and Pacific cultures.

DIFFERENT PRESENTATIONS OF EMOTIONAL DISTRESS

People from all cultures experience both somatic and psychological symptoms when emotionally distressed[9]. One reason for a more somatic presentation may be that this is seen as a more appropriate focus for medical consultation by some cultures. Second, there may be a continuum of experience and interpretation, with the more "somatizing" cultures at one end and the more "psychologizing"[10,11] at the other. Thirdly, a large number of "somatic" complaints are actually metaphors for mental distress. Many of these relate to heart discomfort (e.g. a heart that is "sinking" or "uncomfortable")[12–14] and to abdominal sensation[15,16].

Culture-bound syndromes usually represent cultural explanations for recognizable psychoses or neuroses[13]. For example, Dhat, a belief that semen is leaking from the body in urine, is a complaint in India. It may be a presenting feature, and is used as an explanation for weakness due to depression or organic disease.

DEPRESSION

There has been much debate about the existence of depression as a universal cross-cultural category[10,17]. It is reasonably established that depressive disorders exist across cultures and are strongly related to local constructs[15,18,19]. However, symptoms vary (e.g. depressed older Jamaicans and African-Americans describe feeling "low", "bad" or "fed-up")[20,21]; multiple somatic symptoms or metaphors may be presented; and some cultures may emphasize their explanation (e.g. social or spiritual) for their symptoms[22]. The validity of screening scales may vary, e.g. a lower cut-off point for the Geriatric Depression Scale has been recommended for older African-Caribbeans, African-Americans and Mexican-Americans[23,24]. Symptom profiles in depressed cases may also differ considerably across cultures, as shown even across European centres in older people[34]. Depression at community level also appears to be highly correlated with anxiety[25]. The implications are that: (a) it is important to enquire about the *full* range of affective and neurotic symptoms; and (b) a wide definition of mood disorders is likely to be most useful in the clinical setting.

FUNCTIONAL PSYCHOSES

Psychotic symptoms and signs appear similar in form across a wide variety of settings[26], although the content, e.g. of delusions, will be influenced by culture. Also, of course, the patient and his family's explanation for the illness will depend on their cultural framework[27]. Hence, someone from Zambia may explain his/her schizophrenia as he/she might explain a stroke, depression or a burglary—as due to bewitchment or to having angered a spirit.

Culturally-supported dissociative states and altered states of consciousness can be misleading[6]. Pseudohallucinatory phenomena have been described in non-psychotic depression, anxiety and distress states[13,28].

An apparently unusual idea, such as believing oneself to be bewitched, is only a delusion if it is out of keeping with the beliefs of others in the culture. This must be checked by asking someone with appropriate knowledge. If faced with the patient alone, ask how he/she came to believe this, and if others close to him/her agree. If a traditional healer told him/her so, and his/her peers agree, then it is at least likely that this is a culturally sanctioned belief. Another error is to assume that a belief is culturally normal when it is actually abnormal.

DEMENTIA

DSM-IV criteria[29] for dementia require the demonstration of cognitive impairment of sufficient severity to interfere with the activities of daily living. However, cultures vary in the extent to which they expect older people to take responsibility, e.g. for domestic activities. Also, impairment from physical conditions is commoner in socially disadvantaged people and will be difficult to distinguish from that due to dementia, requiring greater emphasis on physical examination and tests[6,30]. Many cognitive tests include items affected by education (e.g. requiring reading, writing or arithmetic skills) and/or which may have little relevance in certain cultures (e.g. "Who is the President?", "Take 7 from 100"). When testing those unfamiliar with such approaches, be courteous, encouraging (without "helping"), give explicit instructions and some dummy tasks to allay anxiety[30]. Rather than doggedly adhering to the original version of instruments, it is appropriate either to make rational adaptations (as described for the MMSE[35]) or to develop new instruments[31]. Novel adaptations will, of course, require translation, back-translation and pre-testing[33]. Suitable informants should be screened for any decline in function of their close contact[32]. The Community Screening Instrument for Dementia[31,33] combines culture-fair cognitive testing with a structured informant interview. This approach should become more routinely applied, both in primary and secondary care.

Depression in the Indian Subcontinent

Vikram Patel

London School of Hygiene and Tropical Medicine, London, UK, and The Sangath Society, Goa

Common mental disorders, such as depression in late life, are not well understood or acknowledged by either the community or the medical profession in India, for three important reasons. First, recognition of common mental disorders as a psychiatric problem in general is relatively poor. Most patients present with somatic symptoms. While many patients and health providers acknowledge the non-organic basis of these symptoms, neither group is comfortable with labels that imply a relationship to psychiatry. Indeed, terms such as "depression" and "anxiety", when used to define diagnostic categories of psychiatric disorder, have no conceptual equivalent in any Indian language. Ethnographic studies have shown that symptoms of depression are attributed to tension, family conflict and lack of family affection, rather than being seen as a biomedical psychiatric problem[1]. The second reason for low recognition is that the relative proportion of elders is less than 5% for most Indian communities. This is bound to change in the future, with falling birth-rates and rising longevity leading to predictions that, over 20 years, this oldest sector of the population will exceed 100 million. The implications are grave, for India has no systematic social welfare system for the aged, and is faced with the gradual breakdown of traditional extended family systems that have formed the bulwark for the care of the disabled and chronically ill[1]. The third reason is:

> the fatalistic attitude toward aging in India, which mandates that elderly persons accept their physical and mental condition as a normal part of old age. Not only are elderly persons with mental illnesses rarely brought to a physician, but those with treatable medical conditions also often receive no medical attention[2].

There are few epidemiological studies of common mental disorders in elders in India and no published studies, to date, that have used structured psychiatric interviews. Prevalence rates for depression in a community sample of elders have varied from 6% in southern India[3] to over 50% in rural West Bengal[4]. The common presenting complaints are tiredness, sleep complaints, aches, tingling-numbness in the hands and palpitations. On enquiry, however, most depressed elders will admit to cognitive and emotional symptoms typical of depression. The hallmark cognitive feature is anhedonia, or loss of interest. Suicidal feelings and agitation are also common[3]. The suicide rate in the 50+ age group (12/100 000) is nearly twice the national average (7/100 000). Co-morbidity with physical ill-health is common; by some estimates, more than 90% of elders with a psychiatric disorder also have some physical disorder[3]. Risk factors for depression include low education, poverty, social isolation and family discord. The latter is on the rise as a result of the breakdown of traditional community structures resulting from the massive migration of the younger productive members of families to urban areas and reduced economic activity in rural areas. The commonest treatments in primary care are symptomatic. Thus, benzodiazepines for insomnia and vitamins and "tonics" for tiredness are amongst the commonest prescriptions for common mental disorders in general health care, while antidepressants or psychotherapy are rarely offered[5].

The rising rates of recognized risk factors, relatively low recognition of depression and even lower rates of appropriate interventions should cause considerable concern to public health policy and planning in India. One major limitation in influencing policy and practice is the lack of systematic evidence of the epidemiology of depression, and the efficacy and cost-effectiveness of treatments for depression, in elders in India. Research into the mental health needs of elders in India is clearly an important area for future psychiatric research. Health education should aim to educate health workers and the community to recognize that anhedonia and insomnia are not the expected price of growing old, but the result of a common, disabling and treatable illness. Removing stigma may require integrating the subject of depression into training programs for community and general health workers, and collaborating with non-governmental organizations that are pioneering programs to empower the elderly, support families with a mentally ill elder and provide health care sensitive to their needs. Working with the existing manpower and health and social service infrastructure is likely to be more successful in meeting the mental health needs of elders in India than developing specialized psychogeriatric services throughout the country.

Dementia in the Indian Subcontinent

S. Rajkumar[1], M. Ganguli[2] and D. V. Jeste[3]

[1]*University of Newcastle, NSW, Australia,* [2]*University of Pittsburgh, PA, USA, and*
[3]*University of San Diego, and VA San Diego Healthcare System, CA, USA*

Of India's population of nearly one billion, 50 million are aged 65 years or older and constitute a major potential high-risk group for dementia, yet pathological studies of dementia in India suggest that Alzheimer's disease (AD) is rare or unrecognized in most clinic populations. The few published epidemiological studies of dementia from India suggest potential regional differences in prevalence, which may be partly attributable to literacy or urban/rural residence. Differences across studies may also reflect methodological difficulties and differences. Psychometric and other screening instruments must be standardized in different Indian languages for elderly populations with widely varying levels of literacy, education and urbanization. Older individuals frequently have inadequately corrected sensory impairments, which can interfere with testing. They may have little interest in current national or world events, and thus appear to be impaired, and may not know their dates of birth. Cognitive deficits may be under-recognized and under-reported by family members, out of respect for, as well as reflecting low expectations of, the elderly. Prevalence rates of dementia from different studies in India[1–5] have ranged from a low of 1.36% to a high of 3.5% among those aged 65+. These low rates were found despite the use of highly standardized instruments for case detection, e.g. the GMS–AGECAT program and the community version of the GMS at the Madras site of a WHO multicenter study[4].

Lower prevalence may be due to shorter life expectancy, with selective survival of those not at risk for dementia, and also to shorter duration or survival with the disease. Survival may be underestimated if the manifestations of dementia are detected late or attributed in their earlier stages to normal aging. Plausible risk factors yet to be explored in Indian populations include head trauma, thyroid disease and illiteracy. Potential protective factors might range from family caregiving to low-fat diets. Tolerance of memory loss in old age, as well as lack of financial resources, may delay acceptance of treatment across the majority of Indian communities. Although prevalence is low, dementia may still pose a major public health challenge given the vastly growing population, the minimal existing infrastructure and the transitions in family structure in these regions.

Dementia and Depression in Africa

Olusegun Baiyewu
University of Ibadan, Ibadan, Nigeria

Africa is a multicultural, multiracial society, consisting mainly of Negroid people, although Arabs predominate in the north and white settlers constitute a minority in the south. There are no policies and programmes for old age in most countries of Africa, and the majority of elderly people live in often neglected rural areas. Most older Africans are impoverished, have little or no education and depend on their children for sustenance. Provision for their medical care is grossly inadequate. In this chapter the situation of the elderly in Nigeria will be used as a prototype for Africa.

Only about 3% of Nigerians are aged 65 years and older[1]. The thrust of healthcare policy is towards communicable diseases in children, and geriatrics and geriatric psychiatry are both in their infancy. About the only policy document regarding old age care states that nursing homes will be discouraged, while home visits to older citizens will be encouraged and day care centres will be established. Federal, state and local governments are expected to share responsibilities for the care of older citizens[2]; however, as with most policies, there is a big gap between conception and implementation.

RESEARCH

Although geriatric research is limited, a number of studies have looked into dementia and depression. Because of the low level of education, most questionnaires designed in Western societies will require modification before application to older persons in Africa, especially in those that measure cognitive functions. Role expectations of older persons are also different, e.g. they are not expected to do household chores in the multigenerational living arrangements which are popular.

Dementia

Initial publications on dementia in Africa were about hospital patients, Lambo[3] in Nigeria and Ben-Arie *et al.*[4] in coloured older persons in South Africa. An earlier community study on dementia created the impression that Alzheimer's disease (AD) was rare or non-existent in Nigerians[5]. This conclusion is probably related to methodological issues in the study.

A major community-based study comparing older African-Americans in Indianapolis with older Nigerians in Ibadan has been ongoing since 1992. Prevalence rates of both dementia and AD were significantly higher in Indianapolis compared with Ibadan, 4.82% vs. 2.29% for dementia and 3.69% vs. 1.41% for AD[6]. More importantly, there was a progressive increase in the prevalence rates of both dementia and AD with increasing age after 65 years. Another important finding was that the Apoe4 allele, which has been reported to be associated with AD in most studies, was found to be unrelated to AD in Nigerians[7]. Important risk factors for dementia in Nigerians included age and female sex only; other well-known risk factors were not identified[15]. Behavioural disorder symptoms were found both in Nigerians and African-Americans but it was felt that Nigerians are generally more tolerant of behavioural disorder symptoms in their demented family members, who are often not treated[8].

In another major community survey of people aged 60+ in Egypt, Farrag *et al.*[9] reported a prevalence rate of 4.5% for all dementias, 2.2% for AD and 0.9% for multi-infarct dementia. In that study also the rate of dementia doubled every 5 years.

Depression

Lambo[3] diagnosed more depression in hospital older male patients compared to older females; Baiyewu *et al.*[10] reported that 5.4% of older Nigerians were depressed in a community survey with a preponderance of males. Recently, Sokoya[11] also showed that 5.4% of older primary care attendees were depressed, using AGECAT criteria[12]. Depression was related to low income but there was no gender difference. Depression was not often recognized and treated.

Nursing Homes

Nursing homes are very few in Nigeria, as in other African countries. However, in a study of psychiatric disorders in two Lagos nursing homes, using AGECAT and DSM-III-R[13] diagnoses, 48% of patients had dementia and 17% had depression[14]. Although the sample size was small and it is difficult to generalize, the figures are close to those reported in centres in Western societies, which may portend that the problem will become more evident in future as the number of older persons increases.

FUTURE TRENDS

There have been two major community studies on dementia in Africa; the study among the Arabs of Egypt gave prevalence rates twice as high as for Nigerians. There is an urgent need to have more studies on psychiatric disorders among older persons in Africa. Such studies will be informative on rates, patterns of illness and risk factors, as well as assisting in policy formulation.

Mental Illness in South America

Sergio Luís Blay

Federal University of São Paulo, Brazil

This chapter will present some features of psychogeriatrics in Latin America. With this aim in mind, the situation with regard to epidemiology, risk factors, recognition of symptoms, the influence of culture and the state of development of services will be outlined.

EPIDEMIOLOGY

Depression

Estimates of the frequency of depression symptoms vary widely from 8 to 46.2% (see Table 118.1). Such a variation depends heavily on the instruments used, cut-off points and severity of the symptoms. Using higher cut-off points, Cornejo and Lazlo[1] obtained a prevalence of 8%. Eisirik[2], using the DSM-III-R checklist, found a prevalence of 4.7% for major depression in an urban sample. Women presented higher rates, 5.8% vs. 2% for men.

Table 118.1 Prevalence of depression symptoms in Latin America

Ref.	Age	Instrument	Sample size	Prevalence (%)
16	65+	Zung SRDS	26	46.2
1	68+	Brink GDS	433	8 (severe depression)
3	60+	Short care	738	20.9–36.8
5	60+	MADRAS	62	30
2	60+	MADRAS	344	21.5
—		DSM-III-R		4.7 (major depression)

Dementia

The prevalence of organic brain syndromes varies (4.3–29.7%). The study of Veras and Coutinho[3] investigated three subdistricts of the city of Rio de Janeiro. The figures varied dramatically: 5.9 in Copacabana subdistrict to 29.7 in Santa Cruz. Several socio-economic variables accounted for such differences.

Cognitive impairment ranged from 10.5% to 29%. The study conducted by Xavier[4] relied on the oldest sample (80+) and investigated the age-associated cognitive decline through a neuropsychological battery (19.7%). Silberman *et al.*[5] have found the highest figure (29%) in a small urban community sample.

Herrera *et al.*[6] conducted a survey using a three-stage design in the city of Catanduva in the state of São Paulo. The MMSE was used as a screening instrument. All the suspected cases were further investigated by a specialist, using a set of evaluations. All subjects with a diagnosis of dementia went through a complete laboratory examination; 1660 subjects aged 65+ were interviewed. The prevalence of dementia was 7.1%. In the series of 118 cases, as many as 64 cases (54.1%) were diagnosed as having Alzheimer's disease, 11 (9.3%) vascular dementia and 17 (14.4%) an association of vascular dementia and Alzheimer's disease. The prevalence of dementia was age-associated: 1.3% in the age group 65–69; 3.4%, 70–74; 6.7%, 75–79; 17%, 80–84; and 36.9%, 85+. Education was an important protective variable against dementia. The prevalence rates can be seen in Table 118.2.

Prevalence of Mental Disorders

Ramos *et al.*[7] conducted a household survey using a multidimensional functional assessment questionnaire (OARS methodology); 1062 elderly aged 60+ living in three subdistricts of the city of São Paulo, Brazil, were interviewed. Among other data 27% of the subjects were considered psychiatric cases, as assessed by the mental health screening questionnaire included in the methodology. Eizirik[2], using the SRQ as a screening instrument, observed that 10.2% of subjects were considered positive psychiatric cases in a sample of 344 individuals aged 60+.

Alcoholism

Community studies are mainly focused on adult samples. Data concerning elderly populations are usually restricted to a small number of elderly persons. Yamamoto *et al.*[8], studying an unselected sample in Lima, Peru ($n = 815$), screened seven men (43.75%) out of 29 subjects aged 65+ for lifetime alcohol abuse or dependence.

RISK FACTORS

The Latin-American literature is not extensive in this respect. Epidemiological data[6] have indicated that dementia of the Alzheimer's type occurs somewhat more often in women, in a proportion of 2:1. Sadigursky and Oliveira[9] investigated the association between religious practice and depression on women aged 60+ attending a geriatric clinic. This case-controlled study examined 90 women. They found that the regular practice of religious activities had a protective effect on depression (7.4%) compared with less interested in religious activities (44.4%).

Table 118.2 Prevalence of dementia in Latin America

Reference	Age	Instrument	Sample size	Prevalence (%)
Organic brain syndromes				
18	55+	QMPA	139	4.3
	65+		44	6.8
12	65+	FHT	91	5.5
3	60+	Short care	738	5.9–29.7
Cognitive impairment				
5	60+	MMSE	62	29
2	60+	MMSE	344	24.7
4	80+	Battery	77	19.7
17	60+			10.5
Dementia				
6	65+	MMSE	1660	7.1

Studies of adaptation to high altitudes have led investigators to examine whether altitude itself is associated with mental problems in late life. Countries like Peru or Bolivia have a peculiar geography suitable for these type of studies. They have communities living both at sea level and at 4000 m above sea level. Alarcón *et al.*[10] examined 93 subjects aged 60+ living in Lima (150 m) and 140 in Cusco (3400 m). Among other findings, they verified that the frequency of symptoms of anxiety and cognitive decline was greater at high altitudes than at sea-level.

RECOGNITION OF SYMPTOMS AND THE INFLUENCE OF CULTURE

An ethnographic study conducted in north-western Brazil examined the meaning of sadness in this low-income population. This qualitative study, which included retired subjects aged 60 years, found three main semantic clusters for sadness: an inner set, the body set and the interaction set[11].

Cross-cultural comparisons between unselected samples of elderly in two urban populations, Mannheim, Germany, and São Paulo, Brazil, using similar instruments, found similar symptom profiles in both cities. Some disparities between the samples are thought to be real and to relate to sociocultural differences as well as the greater stresses of daily life in São Paulo[12].

STATE OF THE DEVELOPMENT OF SERVICES

The pattern of service utilization in Latin-America by older patients with mental health problems is not well known. Few studies have investigated the ability of primary care services to meet the demand[13] and to determine different potential users' expectations and needs[14]. It is reasonable to suppose that important inter-regional differences exist in the delivery of care. In some places the only source of available psychiatric treatment is the hospital, generating a misuse of psychiatric resources[15].

Psychiatry of the Elderly—the WPA/WHO Consensus Statements

Cornelius Katona

Royal Free and UCL Medical School, London, UK

Between 1997 and 1999, under the Chairmanship of the late Professor Jean Wertheimer, the World Psychiatric Association, Section of Geriatric Psychiatry, published a series of consensus statements in collaboration with the World Health Organization Division of Mental Health. A wide range of non-governmental organizations (NGOs) participated.

The first Consensus Statement[1] defined the scope of the specialty, emphasizing that this has become necessary because of increasing longevity (most markedly in the developing world); the relatively high prevalence of both functional mental disorders and the dementias in old age; and the need to adopt a multidisciplinary approach, while defining professional roles within the team. The scope of psychiatry of the elderly is "the psychiatry of 'retired' people", and includes the full range of mental illnesses, including affective disorders, psychoses, substance abuse, the dementias and the mental health problems of "graduates" whose mental health problems continue into old age. The specialty also needs to address psychological, physical and social aspects of mental health problems in older people and the biosociocultural changes associated with ageing.

The characteristics of a successful psychiatry service for the elderly are summarized as community orientation, a multidisciplinary approach, an emphasis on abilities as well as deficits, and a core aim to improve quality of life rather than simply to alleviate symptoms. The main objectives of treatment are the restoration of health, improvement of quality of life, the minimization of disability, the preservation of autonomy, and addressing the needs of family and other carers as well as those of the individual patient. The high relapse rate of functional psychiatric problems in old age necessitates close follow-up after successful initial treatment.

Priorities within any new specialist service include teaching psychiatry of the elderly to primary healthcare workers; training existing mental health professionals in special mental health problems of the elderly, and establishing at least one multidisciplinary resource/expertise centre.

The second Consensus Statement[2] identified general principles that should underpin any quality specialist psychiatry of the elderly service:

- Good health and optimal quality of life are fundamental human rights irrespective of age or mental disorder
- All people have right of access to appropriate services
- Recognized needs should, within resource constraints, be met appropriately and ethically
- This can only be achieved through health and social measures adapted to local needs
- Older people with mental health problems and carers should be involved, individually and collectively, in care planning
- Governments should recognize the crucial role of non-governmental organisations and work with them.

The specific qualities of a good service are that it should be Comprehensive, Accessible, Responsive, Individualized, Transdisciplinary, Accountable and Systemic (CARITAS), and should attempt to both prevent mental health problems from arising and identify them early when they do arise. As well as offering comprehensive assessment and acute management, the service should provide continuing care and support to patients and carers and address spiritual and leisure needs as well as medical needs.

The third Consensus Statement[3] focused on education. Targets for educational initiatives include: health and social care professionals at undergraduate, postgraduate and continuing education levels; health and social service managers; other care workers; family and other informal carers; voluntary workers; public policy makers; and the general public. Although such a wide range of target groups inevitably start with different needs and different starting levels of knowledge, a generic core curriculum can be derived from the learning needs of health professionals. Essential curriculum elements include:

- Processes of ageing in individuals.
- The demography, economics and politics of ageing societies.
- The epidemiology, pathology, clinical features, assessment, diagnosis, treatment and management of the mental disorders of old age.
- Physical disorders and impairments of function that commonly occur in old age.
- The special significance in old age of the interdependence of mental, physical and social factors.
- Principles of health promotion and the preventive psychiatry of old age.
- Ethical and legal issues relevant to older people.
- Principles of planning, provision and evaluation of services in different settings.
- Needs of carers and approaches to their support.
- End-of-life issues.
- Principles and practice of multidisciplinary teamwork.
- Interviewing and communication skills.
- Fostering of positive attitudes and insight into the reasons for negative attitudes.

Development of Health and Social Services in the UK in the Twentieth Century

John P. Wattis
University of Huddersfield, Huddersfield, UK

IMPERIAL BEGINNINGS: THE POOR LAW AND THE ASYLUM

In Britain, the twentieth century dawned in a blaze of imperial glory. Three years earlier, Queen Victoria's diamond jubilee had been celebrated across the globe with a splendid procession in London itself. The mood of the nation was confident, even optimistic, and world-domination was accepted almost as a birthright of the British people. Britain had survived the rigours of the Industrial Revolution and had come up fighting. Yet, at this time, public health measures were rudimentary and confined largely to the establishment (in 1848) of sanitary authorities with medical officers of health to oversee sewers and water supplies. The poor law was still in force and poor law institutions were made deliberately unpleasant. This followed the principle of "lesser eligibility", set out in 1834, which stated that those receiving poor law assistance should not be as "eligible" (well provided for) as an "independent labourer of the lowest class"[1]. For the poor sick this had been ameliorated, to some extent, by the setting up of poor law infirmaries in 1868, but there was still a vast gulf between these institutions and the voluntary hospitals, which were supported by rich philanthropists. Retirement pensions, even retirement itself, were things of the future and there was an association between poverty, ill-health and old age which was recognized by an 1895 Royal Commission on the aged poor.

Mentally ill people were still incarcerated in large county asylums. In 1808, partly as a response to the appalling conditions in some private "madhouses", local magistrates had been given the power to set up asylums and in 1845 this provision had been made mandatory.

From 1900 onwards, developments have been influenced by major world events, political philosophy, public opinion and the power of pressure groups. The Boer War, starting in 1899, revealed the poor physical fitness and ill-health of many young men. Improvements in midwifery and child care were soon legislated for, with school meals starting in 1906 and the notification of live births, health visiting and the school medical service soon following. In 1908 the first national scheme for old age pensions was set up to try to alleviate poverty amongst old people. It was non-contributory and means-tested. Initially, recipients also had to be "of good character"!

The Royal Commission on the Poor Laws and the Relief of Distress in 1909 considered most of the issues of domiciliary and hospital medical care. A minority report condemned the poor law institutions as a public scandal, with the infirmaries understaffed and lacking skilled medical input[2]. Out of hospital, the poor law doctors had no contact with local authority public health services, the voluntary dispensaries were overcrowded and ineffective and the medical clubs, financed by workers' subscriptions, underpaid their doctors and did not cater for the chronic sick or dependants. The writers of this report dismissed the idea of a medical insurance system.

Yet, in 1911, the establishment of such a system marked an important development in the evolution of general practice in the UK. The medical profession fought for, and won, independence and capitation fees rather than a salaried service, and administration by insurance-based panels rather than local authorities[3]. Higher income groups, families and hospital care were excluded but the scheme was nevertheless a qualified success.

THE MINISTRY OF HEALTH: BETWEEN THE WARS

In 1918 the Ministry of Health for England and Wales was formed and the Minister quickly appointed a consultative council, which in 1920 produced a report described by Pater[2] as "nothing less than the outline of a national health service" (p. 7). Their scheme might well have avoided some of the split between general practitioners and hospital doctors that has been one of the problems of the National Health Service (NHS) as it was eventually implemented.

Control of the workhouses passed to local authorities in 1930, the beginning of the end for the poor law. After a post-war cash crisis, the voluntary hospitals continued, becoming more specialized in acute care and leaving the chronic sick and infectious diseases to the local authorities. A number of reports pressed for a more coordinated hospital system and for universal health insurance. Knowledge was advancing. In 1935 Warren[4,5] began her work in developing geriatric medicine and, a few years later, pioneers began to write of the issues concerning old people with mental illness[6–8].

Before the Second World War, the Emergency Medical Service (EMS) was set up to cope with expected severe civilian casualties from the bombing of cities. On the declaration of war, 140 000 people, many of them elderly, were discharged from hospital over 2 days[9]. The EMS also coordinated the work of the voluntary and local authority hospitals, providing the framework for the future NHS Regional Hospital Boards. Physicians and surgeons from the elitist voluntary hospitals came face to face with the conditions of the poor law institutions.

THE POST-WAR NATIONAL HEALTH SERVICE

The last of the series of British Medical Association (BMA) reports pressing for reform in 1942 coincided with the Beveridge report and was followed in 1944 by the NHS White Paper, enacted in 1946 and effective in 1948.

The National Health Service, as then set up, was tripartite. Primary care services—general practitioners, opticians, dentists and pharmacists—were answerable to local executive committees; maternity, child welfare, health visiting, health education, immunization and ambulances remained the responsibility of the local authority; and hospitals were administered by Regional Hospital Boards with teaching hospitals retaining boards of governors directly answerable to the Ministry of Health. One of the assumptions when the NHS was set up was that increasing health in the population would cause health expenditure to level off. It never did, and in 1956 the Guillebaud Committee, appointed to find ways of avoiding a rising charge upon the exchequer, concluded that there was no evidence of inefficiency or extravagance in the NHS. In fact, the committee was concerned about a lack of capital expenditure (a concern again of relevance more recently). In 1962, this problem was addressed in the Hospital Plan.

Meanwhile, in the mental health field, the idea of community care was gaining ground. Tinker[10] attributed this to five factors. First, there was a general dissatisfaction with institutional care and a search for alternatives. Some of the experiments in the "therapeutic community" work of the Second World War had challenged the accepted authoritarian culture of the mental hospital[11]. In addition, the advent of electroconvulsive therapy (ECT), antipsychotics and effective antidepressants facilitated the move away from custodial care to medical treatment at home or in ordinary hospitals. Next, there were beginning to be practical problems in running residential establishments, including staff recruitment. Then there was concern about the cost of institutional care and, finally, a recognition that mentally ill people were entitled to live in as normal a way as permitted by modern treatments. The 1959 Mental Health Act liberalized the treatment of mentally ill people and opened the way for a move away from the old psychiatric hospitals to the new concept of psychiatric units attached to the district general hospitals of the 1962 Hospital Plan.

The large institutions were, in any case, rocked by a series of scandals about the mistreatment of patients. This resulted in the establishment of the Hospital Advisory Service (later the Health Advisory Service), effectively an inspectorate to monitor standards and spread good practice.

In general practice, a financial allowance for practices in deprived areas combined with other factors to promote the rapid development of local health centres and group practices from the mid-1960s. Local authorities produced their own health and welfare plans but there was poor coordination with the hospital authorities and the general practitioners' executive committees. Within the local authorities, the Seebohm report (1968) was followed by the Social Services Act, which required the setting up of social services departments. The Department of Health and Social Security was created in 1968 by the amalgamation of the Ministries of Health and Social Security, a merger that lasted for some 20 years.

Reforms

In 1974, for the first time since its inception, the NHS itself was reorganized. The chief elements of this reorganization were the separation out of health and social services functions, the integration of all health functions under one management and the establishment of area health authorities, generally co-terminous with local authorities, to facilitate joint planning. Community Health Councils were also created to represent the views of consumers. Unfortunately, the reformed service did not work well. There were too many layers of responsibility and taking decisions seemed to be delayed whilst information and responsibility were passed up and down the tree. There was an increase in clerical and administrative staff without a corresponding increase in managerial efficiency. During this period, important government reports were produced, including *Better Services for the Mentally Ill*[12] and *A Happier Old Age*[13].

In 1982 the Area Health Authorities were abolished and new district health authorities combined the functions of the old areas and districts. In some areas, co-terminosity with local government was lost. A new government was determined to cut public expenditure and the rate of growth of the NHS slowed. Following the Griffiths report[14], a general management structure was established within the NHS and Family Practitioner Committees became independent. Government payment for continuing care was channelled to the private sector and social services and hospital provision for this group of patients/residents was either reduced or failed to keep pace with demographic changes[15].

Psychiatric services were coping with the implementation of the 1983 Mental Health Act, which set up time-consuming quasi-judicial procedures for reviewing patients who were detained in hospital under compulsory orders. The new Act also set up a Mental Health Act Commission to review treatment of detained patients and to advise on certain types of treatment.

MARKET FORCES: A RADICAL DEPARTURE?

Then came the most radical reform of the NHS attempted to that date, a reform not just of the service but of the basic philosophy of "service" underlying it. Some suspected that it was the beginning of the end for the National Health Service. The 1990 National Health Service and Community Care Act introduced the concept of an "Internal Market". The new health authorities became planners and purchasers of health care at "arm's length" from the providers, which were initially directly managed units (DMUs), and became semi-independent Trusts. The health authorities were provided with a budget for the local population and placed contracts for care with Trusts or the private and voluntary sector in order to obtain the best "value for money". Quality was, at least in theory, specified in the contract and monitored.

Competition and other features of business life were "introduced" into the NHS, not least by setting up groups of "fundholding" general practitioners, who were enabled to make their own contracts for secondary care. Some of the changes were potentially positive, such as the setting up of Trust Boards to manage local services and an emphasis on sound financial regulation through corporate governance. Unfortunately, the bottom line was very clearly financial and in many cases clinical services were sacrificed to balance the books.

These proposals were pushed through in the teeth of strong opposition from staff and groups representing the consumer. Honigsbaum[16] analysed the situation in 1990 and concluded that if patient care suffered, then "the nation may decide that the restraints imposed are not worth the savings they produce. Today, as in 1911 and 1948, it is the public interest that will predominate". The medical profession were excluded from the plans for this reorganization. Klein concluded that, if a new political settlement were not reached between the government and the profession, it seemed unlikely that the NHS would survive long into the twenty-first century[17].

A NEW NHS?

In fact, perhaps partly because of public disatisfaction with what was happening to the NHS, the government was not re-elected and a radical reforming Labour government came to power. The engines of privatization and the internal market were reversed and new reforms were produced. In December 1997 a White Paper, *The new NHS: Modern, Dependable*[18], outlined a comprehensive new vision for the NHS. Two of the main planks of the new policy were the setting up of primary care groups (PCGs) to replace the fundholding/non-fundholding split and the introduction of comprehensive quality controls to ensure high standards and equity in access across the country. PCGs are local groupings of general practices that are involved in the commissioning of local community and secondary services and may eventually become Primary Care NHS Trusts, providing community services and commissioning secondary services. More recently still, the concept has been developed of "Care Trusts which could provide primary care and some secondary services, such as mental health services". The quality framework involves a three-layer approach[19]. Clear standards of service will be set by National Service Frameworks and a National Institute for Clinical Excellence (NICE), which will evaluate new treatments. An SF for Older People was published in 2001[20]. The first of eight standards was "rooting out age discrimination". The seventh concerned mental health and included NICE guidelines for anti-dementia drugs. The new NSF made it clear that standards in the Mental Health NSF already published applied to older people. Local delivery of services will be made dependable by a combination of lifelong learning[21] linked to professional self-regulation and clinical governance. Clinical governance[22] places obligations on Chief Executives of NHS Trusts to make arrangements to monitor and continuously improve the quality of health care they provide. Finally, all this will be underpinned by the national monitoring of standards involving a National Performance Framework, an inspectorate (the Commission for Health Improvement) and a National Patient and User Survey. This ambitious vision sets a massive agenda for change and demands radical shifts in the management and clinical cultures of the NHS of a magnitude that will not easily be achieved[23]. Without adequate resources, these well-intentioned reforms may well overload the capacity for change of both managers and clinicians working in the NHS.

Primary care groups (in England) result in a much greater influence for general practitioners and other primary care workers in the commissioning of secondary services. Their boards are dominated by primary care workers. When they become Primary Care Trusts, good corporate governance demands a board structure with executive and non-executive directors, more analagous to the boards of existing Hospital and Community Trusts. This will result in general practitioners effectively losing their quasi-independent status. The Trusts are likely to be direct providers of many community services currently provided by Community or Community and Mental Health Trusts. In Scotland, where different arrangements pertain, mental health is part of primary care groups, but they do not control the budgets of secondary care Trusts in the same way as in England. In Wales the arrangements are closer to those in England. In England and Wales it seems likely that, in the larger cities at least, "stand-alone" Mental Health Trusts will be the order of the day. For old age psychiatry, this probably means that the managerial separation between old age psychiatry and geriatric medicine will be perpetuated. Unless imaginative and pragmatic solutions are found, this could result in many demarcation problems. However, a new culture of collaboration rather than competition and a government apparently committed to encouraging "joined-up" thinking and working means that these difficulties may be overcome.

The funding of the NHS is probably even more important than its organization in determining the future of health care in the UK. It was the squeeze on NHS development in the 1980s that provoked the medical profession to campaign for more development money. In the light of international comparisons, both of spending on health care and the age structure of the population, this campaign seemed fully justified. The previous reorganization increased management costs and reduced the morale of many in the NHS. So far, although the new government has promised more capital investment in the NHS, it has continued to support the controversial Private Finance Initiative (PFI) as a main strand of funding, which reduces the Public Sector Borrowing Requirement. There is concern that PFI will result in a reduction in bed numbers and diversion of money away from services to support repayments to private providers in respect of capital developments. If more money for services comes with the new reorganization, then the potential for positive change exists. If it does not, then the new reforms, like the Internal Market before them, are doomed to failure. Another problem with introducing improvements is the shortage of trained staff. The government has recognized the need to train more doctors and nurses, but it will take time to turn this recognition into staff-delivering services.

OTHER INNOVATIONS

The direct reforms of the NHS have been accompanied by a Royal Commission to review long-term care. The report of this Commission[24] controversially suggested that the personal care and residential elements of continuing care should be separately funded. Personal care should be paid for from general taxation, whilst living and housing expenses should continue to be means-tested and subject to co-payment. The government has yet to make an unequivocal positive response to this. Standards in psychiatric services for old people continue to improve generally but it remains to be seen whether the latest reforms will ensure that quality is universally high and that funding is adequate.

The Pattern of Psychogeriatric Services

John P. Wattis

Leeds Community and Mental Health Services, Leeds, UK

HISTORIC BACKGROUND

The roots of the National Health Service (NHS) and the development of psychogeriatric services in the UK are discussed in the previous chapter. The evolution of psychogeriatric services has been guided by professional knowledge and opinion, by the politics of the health and social services, by financial constraints and, occasionally, by public opinion. From the inception of the NHS, which effectively antedated the beginning of provision of specialist psychogeriatric services until the 1990s, there was a consensus about how developments in services should occur in response to changing demography and epidemiology as well as advances in medical knowledge.

This consensus was threatened in the UK by the imposition of the ideology of "market forces". Much long-stay hospital accommodation was effectively "privatized" by decisions to support patients in private nursing and residential homes from state funds and to close down as many long-stay NHS beds as possible. The ideology of market forces was briefly applied to local authority provision of community care. Since April 1991, psychiatric patients with social needs have been subject to a "care-planning procedure" in which all parties, including social services, have to agree. In April 1993 the full implementation of the Community Care Act made local social services departments responsible for purchasing continuing nursing and residential home care, largely from the private sector and with a limited budget.

In the late 1990s, a government came to power that did not share the vision of market forces as the best way to regulate the NHS. This government emphasized *equity* and *quality* and returned to a modified vision of the NHS as a centrally regulated nationalized service industry. It is not certain that the opposition shares this vision, and so there is a danger of the NHS remaining a "political football". For the time being, though, despite the distractions provided by problems in under-resourced psychiatric services for working-age adults, it seems likely that the conditions in the NHS will again be more favourable to the growth of old age psychiatry services, which are essentially a collaborative rather than a competitive enterprise.

THEORETICAL BASIS FOR PSYCHOGERIATRIC SERVICES

The pioneers of specialist psychiatric services for old people were motivated by the increasing need for psychiatric services for the age group, consequent upon increased life expectancy, the growing knowledge base about psychiatric disorders amongst old people, and the success of geriatric medicine. The special needs of older people were not always recognized by the generic services. Diagnostic problems included the differential diagnosis of dementia, the association of apparent cognitive impairment with some cases of depressive illness, and the non-specific presentation of disease in old people. The multiple pathology suffered by old people led to a need for new patterns of multidisciplinary working and for close liaison with physicians in geriatric medicine and social services[1–3]. As in the early days of geriatric medicine, assessment and treatment in the community were emphasized not only because of "blocked beds" but also because a more realistic picture of the patient's health problems usually emerged. More recently, advances in psychosocial care[4], interest in the spiritual needs of old people[5] and the advent of new classes of antidepressant, antipsychotic and antidementia drugs (discussed elsewhere in this volume), have all had their impact on the organization and delivery of psychiatric services.

CARE OR TREATMENT—PRIMARY OR SECONDARY?

One of the key theoretical issues for the future development of community services is likely to be the distinction between care and treatment. "Care" is a word with many connotations. Some are positive but, in the medical world at least, some are negative. For example, "care" is seen as what is provided when there is no possibility of effective treatment, as in the "prescription" of "tender loving care" for the terminally ill person. "Care" tends to be relegated to untrained (although not necessarily unskilled) workers employed by Social Services, whereas "treatment" is the province of highly trained personnel employed by the Health Service. The move to "Care in the Community" may serve to reclassify older mentally ill people as not needing medical treatment, and this will have to be resisted vigorously.

This situation is further complicated by the tendency of some health planners to equate primary care with *low cost and community care*, and secondary care with *high cost and hospital care*. Old age psychiatry services straddle the hospital–community divide and provide essentially secondary services, largely in a community setting. The new term, "intermediate care", describes well some of these community services, but some who use the term believe that community psychiatric nursing services should be part of "primary care", when in fact they work most effectively as part of secondary community care.

KEY COMPONENTS OF PSYCHOGERIATRIC SERVICES

Catchment Area and Comprehensiveness

Virtually all psychogeriatric services in the UK work to a defined geographical catchment area and the vast majority aim to provide a comprehensive psychiatric service to all people over the age of 65 years[6,7]. Many services are now also trying to provide for people with early-onset dementia, although often without any dedicated resources[7].

The Multidisciplinary Team

For some this is an outmoded concept, for others an ideal that cannot be obtained, but for many psychogeriatricians it is an essential context for all their endeavours. Most multidisciplinary teams for the elderly incorporate *community nurses*, a *social worker*, one or more *occupational therapists*, a *physiotherapist*, and often a *psychologist*. Various patterns of working have evolved and been described but they have in common an attempt to involve all disciplines in formulating treatment plans for the patient.

Home Assessment

This lies at the heart of most psychogeriatric services. Surveys[6,7] have shown that around two-thirds of referrals were seen at home by a doctor, one-fifth by other members of the team and one-tenth in outpatient clinics. Just over one in 10 were seen as liaison referrals, although in some services this rises to a quarter or even one-third, perhaps partly depending on the admission policies of local geriatric services. Less than one in 20 were admitted direct without prior assessment.

Community Treatment

The rate of acute admissions was only one-third of the rate of referrals, reflecting the fact that most home assessments do not result in admission but in treatment in the community. Home visits by community nurses are probably the commonest form of treatment in the community, although home visits by doctors and other members of the multidisciplinary team also play an important part.

Day Hospitals

In 1985, there were about 1.2 day hospital places/1000 elderly people, and this had not changed significantly by the mid-1990s. Some services and Health Regions had relatively more and others less. The use of day hospitals varied from area to area, depending on the resource availability locally. Anecdotal evidence suggests that government guidelines overestimate the need for dementia places. In many but not all cases of dementia, the need is for *care* rather than *treatment* and so a proportion of this day provision can be provided by Social Services or voluntary agencies. Here, however, issues will have to be addressed as to what kind of care is of most benefit to older people with dementia and their relatives, neighbours and friends. Elderly people with functional illness often have problems with psychiatric or psychological management that demand the *treatment* resources of a true day hospital.

Acute Inpatient Beds

The national rate of provision in 1985 was around 1/1000 elderly served, and again did not vary much over the next 10 years. This may be insufficient to cope with the increasing demands caused by demographic changes and the relative loss of long-stay beds but a great deal depends on the community services available, since there is potential for considerable "marginal shift" between community and inpatient resources. One study showed that around a quarter of acute psychiatric beds for all age groups were occupied by elderly people with depressive illness, and in many areas anecdotal evidence suggests that a greater proportion of acute psychiatric beds are being used for functional illness, principally depression. As with day hospital places, it appears that the old guidelines may have overestimated the needs for dementia assessment beds and underestimated the needs for patients with depressive illness and other functional illnesses. Because of the high prevalence of physical illnesses in mentally ill old people, it is recommended that acute beds should be on a general hospital site. Some services are now beginning to differentiate the assessment and management of behavioural problems in demented people, which can be carried out in the community or in community-based units, from the management of patients with depression, who often have major associated physical illness or disability (and may need ECT) and are therefore better managed on an acute hospital site. The same may apply to atypical dementia patients requiring high levels of investigation or to patients with dementia and delirium. This last group may be best helped on geriatric medical wards.

Long-stay Beds

The provision in 1985 was around 3.4 beds/1000 elderly. Since then a large number of beds appear to have been closed, with patients discharged to the private sector, where developments have been funded through the Social Security budget. In 1996 the number had reduced to around 1.1 beds/1000 elderly. Since provision is largely (but not exclusively) for those with severe dementia, whose main need is for care rather than treatment, this development appears to demand a cautious welcome. Patients are generally being cared for in smaller units. However, there must be reservations. The smaller units are harder to inspect and they are not necessarily in the patients' communities of origin, since planning permission and housing costs enter into the commercial equation. They are subject to capricious changes in the market, including government refusal to pay the "going rate". They are not under specialist medical management and there is some evidence that this management may be one of the factors that reduces the rate of decline in demented elderly people, a factor which, if confirmed, might also have relevance in the day care setting. The switch to private care has been engineered for political reasons and its impact is yet to be fully assessed. Psychogeriatric services will need to retain a proportion of their long-stay beds for rehabilitation, for treatment of old people with resistant functional illnesses (especially depression) and for treatment of behavioural disturbances amongst demented people. A survey of old age psychiatrists[8] showed the majority in favour of around 1.5 long-stay (including respite) beds/1000 elderly in community NHS units, with national rather than local eligibility criteria. The use of such beds for respite care to support carers in the community is now well established, and there is a potential for developing community units as centres of excellence for dementia care, as well as bases for multidisciplinary community teams.

GUIDELINES

The first guidelines for provision of psychiatric services for old people came in a Department of Health circular in 1972[9]. The government White Paper, *Better Services for the Mentally Ill*[10], in 1975, suggested that services for old people should often be provided by a psychiatrist with "a special interest" and incorporated guidelines for bed and day hospital provision for the "elderly severely mentally infirm". Subsequently, the Royal College of Psychiatrists produced guidelines intended to help College representatives reviewing job descriptions for new or replacement consultants. These were endorsed by the Health Advisory Service in its report, *The Rising Tide*[11], and by the joint Royal College of Physicians and Psychiatrists report, *Care of Elderly People with Mental Illness*[12]. The second joint report[13] adopted a more multidisciplinary approach and described the different types of mental illness in old age as well as appealing for equity and "national reference frameworks", which corresponded closely to the concept of "National Service Frameworks" introduced by the new government[14]. It cited "indicative service levels".

REALITY AND GUIDELINES

Although in the UK, old age psychiatry is now recognized as a specialty by the Department of Health, we are still awaiting the collection of routine statistics. Initial manpower statistics appear to be grossly inaccurate. The most comprehensive data available are from the 1985 survey, updated by the 1996 survey, which unfortunately did not achieve such wide coverage. There are also now agreed international standards for old age psychiatry services[15] and an international survey has established that basic levels of service exist in 12 countries worldwide[16].

SPECIALIST SERVICES OR NOT?

In view of the documented rapid expansion of services over the years, this question may seem superfluous. However, it was possible as a result of the 1985 survey to compare services where psychogeriatricians work half-time or more in the specialty with those where the consultant commitment to the elderly is less than half-time[17]. Specialist services had generally higher staffing ratios (with the exception of non-consultant medical staff), a higher proportion of acute beds on general hospital sites and a greater proportion of long-stay beds within the area served. These last two could be regarded as surrogate indicators of quality of care. In addition, the specialist psychiatrists were more likely to look after all mental illness in old age—the recommended pattern of service—to engage in teaching and to show an interest in research.

CONCLUSION

Psychogeriatrics has "come of age" in the UK. Provision, although geographically patchy and relatively under-resourced, still provides one model for future developments. This model, fostered in the National Health Service with its principles of equality of access, payment from general taxation and central planning, survived the major changes of the 1990 "reforms" and should thrive under the regime of equity and quality proposed by the present UK government, always provided that old age psychiatrists show adequate leadership and that governments furnish adequate resources.

Organization of Services for the Elderly with Mental Disorders

Edmond Chiu

University of Melbourne, Victoria, Australia

In 1997, the Section of Geriatric Psychiatry (now Section of Old Age Psychiatry), World Psychiatric Association, with the participation of the Division of Mental Health and Prevention of Substance Abuse, World Health Organization, met at Lausanne to develop a Consensus Statement[1] on the *Organization of Care in Psychiatry of the Elderly*. Under the very able leadership of the late Jean Wertheimer of Lausanne, a multidisciplinary group of leaders in the field produced such a statement. This chapter briefly abstracts and highlights the central issues contained in this document with my personal annotations and explanations in italics.

GENERAL PRINCIPLES

Any organization of care must be founded in firm principles of human rights of the elderly with mental disorders. The historical discrimination towards the mentally ill should be actively fought and the destigmatization of mental illness must be conducted in the context of the unalienable human rights of each individual.

- Good health and life of good quality are fundamental human rights. This applies equally to people of all age groups and to people with mental disorders.
- All people have the right of access to a range of services that can respond to their health and social needs. These needs should be met appropriately for the cultural setting and in accordance with scientific knowledge and ethical requirements.
- Governments have a responsibility to improve and maintain the general and mental health of older people and to support their families and carers by the provision of health and social measures adapted to the specific needs of the local community.
- Older people with mental health problems and their families and carers have the right to participate individually and collectively in the planning and implementation of their health care.
- Services should be designed for the promotion of mental health in old age as well as for the assessment, diagnosis and management of the full range of mental disorders and disabilities encountered by older people.
- Governments need to recognize the crucial role of non-governmental agencies and work in partnership with them.
- Preparing for increasing life expectancy and ensuing health risks calls for significant social innovations at the individual and societal level, which must be founded on a knowledge base drawn from contributions by, and collaboration among, the medical, behavioural, psychological, biological and social sciences.
- In developing countries it may be difficult to provide resources for the provision of care. This, however, does not invalidate the aims of helping the elderly by the application of the principles listed above and the specific principles that follow.

SPECIFIC PRINCIPLES

The acronym CARITAS was deliberately chosen as a cogent reminder that "care and love" underpin these principles. The word "systemic" in some service contexts may be replaced by the word "seamless", representing a service organization that does not permit each individual to fall between gaps.

Good quality care for older people with mental health problems is: Comprehensive, Accessible, Responsive, Individualized, Trans-disciplinary, Accountable, and Systemic (CARITAS).

- A *comprehensive* service should take into account all aspects of the patient's physical, psychological and social needs and wishes and be patient-centred.
- An *accessible* service is user-friendly and readily available, minimizing the geographical, cultural, financial, political and linguistic obstacles to obtaining care.
- A *responsive* service is one that listens to and understands the problems brought to its attention and acts promptly and appropriately.
- An *individualized* service focuses on each person with a mental health problem in his/her family and community context. The planning of care must be tailored for, and acceptable to, the individual and the family, and should aim wherever possible to maintain and support the person within his/her home environment.
- A *trans-disciplinary* approach goes beyond traditional professional boundaries to optimize the contributions of people with a range of personal and professional skills. Such an approach also facilitates collaboration with voluntary and other agencies to provide a comprehensive range of community-orientated services.
- An *accountable* service is one that accepts responsibility for assuring the quality of the service it delivers and monitors this in partnership with patients and their families. Such a service must be ethically and culturally sensitive.
- A *systemic* approach flexibly integrates all available services to ensure continuity of care and coordinates all levels of service providers, including local, provincial and national governments and community organizations.

COMPONENTS OF SERVICE

The concept of "surround with care" as represented by Figure 1, of concentric cycles, provides the concept of service delivery to have as its core the patients and their family carers. By enveloping them with seamless service organization with "permeable" boundaries represented by "dotted lines" in the figure, they are totally supported, and with changing circumstances can move from one service component to another without hindrance.

The described components of service, A–H, when put into place effectively, will meet the international best practice expected by this Consensus Statement.

The components of services can be summarized in Figure 1, which portrays the concept that individual patients, together with family and carers, are surrounded by the care service; these are flexibly interlocking, overlapping and integrated to provide a unified system for continuing care and best possible quality of life. Structural obstacles are minimized, as represented by the dotted lines of the figure, enabling the smooth movement of the patient from one service component to another as changing circumstances require. This section describes the components that can be put into place to address the care needs described in the previous section.

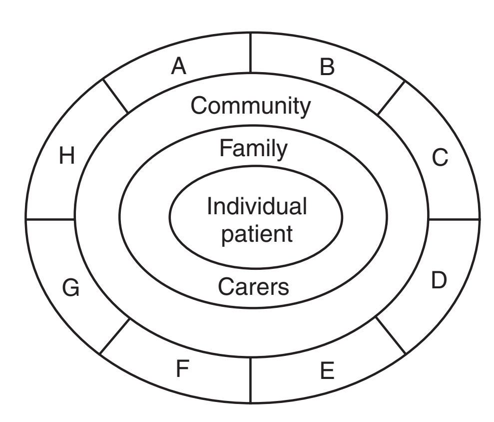

Figure 1 Surround with care

The following components ideally should be the responsibility of specialized teams of trained healthcare professionals working in psychiatry of the elderly. Where there is a scarcity of trained staff and resources, it will be necessary to use *ad hoc* solutions in order to provide the necessary components—while trying to develop services fully.

1. *Community Mental Health Teams (CMHTs) for Older People*. The lead in organizing the following components of the service should ideally be taken by multidisciplinary specialist teams working on psychiatry of the elderly. The CMHT may consist of doctors, psychiatric nurses, psychologists, social workers, therapists and secretaries. Referral to the CMHT is usually from primary care. One of the main responsibilities of the CMHT is the specialist assessment, investigation and the treatment of people in their home setting. In situations where such personnel are not available, the responsibility may be taken by general psychiatric or geriatric medicine teams.
2. *Inpatient services*. Acute inpatient units need to provide specialist assessment and treatment for the full range of mental disorders. This may in some cases include rehabilitation before return to the community.
3. *Day hospitals*. This is an acute service which offers assessment and treatment to older people who can be maintained at home, supported by the multidisciplinary team. The day hospital team could include doctors, nurses and therapy staff. Transport may need to be available.
4. *Outpatient services*. These provide assessment, diagnosis and treatment for people fit enough to live in the community and get to and from the hospital base. Outpatient services should be close to the inpatient and day-patient units. They may involve subspecialty clinics (e.g. memory or mood disorder clinics) and mobile clinics.
5. *Hospital respite care*. Hospital beds may be used to provide a respite service for people with chronic and severe mental illness and associated difficult behavioural problems, in order to give their carers a break and enable care at home to continue as long as possible.
6. *Continuing hospital care*. Care for life in a hospital setting may be required for people with chronic and severe mental illness and associated difficult behavioural problems. Such care should be provided in as relaxed and homely an environment as possible, with carers encouraged to participate.
7. *Liaison services*. Consultations and/or liaison services should be provided between facilities for elderly people with mental disorders and those serving general and geriatric medicine, general psychiatry, residential facilities and social agencies. This relationship should be of a reciprocal nature.
8. *Primary care*. The primary care team has the initial responsibility for identifying, assessing and managing mental health problems in older people. The decision to refer to the CMHT is usually made in primary care.
9. *Community and social support services*. These are services (both formal and informal) to enable the elderly person to remain at home, including a range of activities (home care, day care, residential care, respite care, self-help groups, etc.) provided by voluntary or government/social services.
   (a) *Respite facilities*. A range of short-term, time-limited, in-the-home and out-of-the-home services (residential services, other carers, day programmes) to support the carers.
   (b) *Residential care*. For those patients whose physical, psychological and/or social dependencies make living at home no longer possible, a spectrum of residential facilities should be provided. These range from supported accommodation with low-level supervision, medium-level care facilities, to full nursing facilities. These should be organized to achieve the best possible quality of life.
10. *Prevention*. The mental health team for the elderly should engage in the prevention of relapse of disorders by careful follow-up. They should also identify the risk factors for mental disorders in the elderly (e.g. hypertension, alcohol and substance abuse) and ensure these are effectively managed by appropriate medical, social strategies. Within each service, preventive activities need to be coordinated in collaboration with relevant public health and other healthcare professionals. These may include educational activities to improve early identification of mental health problems by carers, families and primary care personnel in the community.

CONCLUSION

While it may be seen to be less than realistic for some economically less-advantaged countries to achieve this best-practice ideal, nevertheless, both the WPA and WHO would recommend that such an ideal be both aspirational and inspirational. The paragraph:

> In developing countries it may be difficult to provide resources for the provision of care. This, however, does not invalidate the aims of helping the elderly by the application of the principles listed above and the specific principles that follow

in the General Principles section is reiterated here as a reminder that all available resources should be deployed within limited resources. For the "developed" countries that fail to meet these ideals, the WPA and WHO strongly urge their governments, policy makers and healthcare professionals to strive towards satisfying and exceeding the described principles and components of service.

As development of services is always a dynamic process, it is hoped that, in the future, this consensus statement will be reviewed and extended to incorporate improvements and innovations.

The central philosophy is that all elderly people with mental disorders should be provided with the best quality of life and the best quality of care in recognition of their esteemed status as Elders in our society.

The Multidisciplinary Team

Henry Rosenvinge

Moorgreen Hospital, Southampton, UK

Teamwork in the animal kingdom is a behaviour that enables survival. One example of its success is the male emperor penguin, who incubates his precious single egg balanced on his feet for 60 days through the total darkness of the Antarctic winter. This deed is achieved by the emperors huddling together and shuffling around in a constant movement, providing ever-changing relief from the gale-force wind[1].

The ability to behave in such a team has evolved through generations of practice. In care of the elderly in human populations there has been no such tradition and, for those suffering from psychiatric illness, the need for effective teamwork was never more urgent. The problem list presented by the functionally or organically ill elderly patient is often disconcertingly long and complex. The psychiatric disorder cannot be isolated from physical health problems, neither can the patient's functioning be assessed outside the context of his/her own domestic and social situation. Thus, in attempting to treat the patient it is necessary to combine the skills of psychiatric and geriatric medicine, together with those of nursing, clinical psychology, remedial therapy and social work. In many situations, input from the Housing Department, voluntary agencies and the local chaplaincy will be required. The creation of community care packages defined by the UK Government White Paper, *Caring for People in the Next Decade and Beyond*, highlighted the development of teamwork in case management[2]. The UK Government has extended this strategy to include carers as partners of professionals in the planning and delivery of care[3]. Teamwork in the management of the detained patient, particularly in respect of discharge planning and aftercare, are recommended as good practice by the Department of Health[4].

No one profession can attempt to provide all the various skills necessary in the management of every case. It is the relationship between the different professions that is so important. The concept of the multidisciplinary team can be described as a group of members of different professions whose working skills, when combined for the needs of the patient, aim to exceed in quality the simple summation of their individual abilities. Teamwork adds that extra vital ingredient, which needs further exploration.

The multidisciplinary team should be restricted in size to those personnel actively involved in management of cases and in close geographical proximity, to enable face-to-face contact between workers. However, the team should not exist in isolation from other services. The services that collaborate most successfully internally have been shown to not necessarily work best with other agencies[5]. Between different agencies there should be formal liaison and agreed policies over borderline cases and service demarcations.

FEATURES OF SUCCESSFUL MULTIDISCIPLINARY TEAMWORK

Communication

The Personal Social Service Council, in its review of community care, found that failures in communication and negotiation with other agencies led to ignorance of the roles and skills of other professional groups. The organization of care was less good in the more complex situations. As a result, wrong courses of action were taken by some professionals, including inappropriate admissions to both hospital and residential care. The need for joint planning was stressed, particularly between professionals of the different agencies at the operational level[6]. Effective communication is grafted onto the rootstock of mutual trust and respect for the individual roles and skills of other team members. Autonomous decisions, unnecessary duplication of work and stereotyping of one professional by another are thus avoided.

It is important that communication within the multidisciplinary team is afforded formal expression in regular meetings. Too much "corridor" decision making can lead to mistrust. Regular attendance by all personnel complements the identity and strength of the team. This results in the creation of a suitable arena for the airing of grievances and resolving of disputes. Teamwork involves allowing the patient and carer to participate in the process. The therapeutic team could include the patient[7], although the current climate of consumerism in care might be perceived as threatening by some workers.

Leadership

Traditionally, the leadership role in health care is assumed by the senior doctor; this in part reflects society's expectations and faith in the medical profession. Treatment directives may be instigated by the initial medical assessment and form the basis for the leadership role in the clinical team. The dominant role of the doctor in the healthcare team may have a stabilizing effect on the team's structure and prevent leadership struggles by other members[8]. Too hierarchical a structure, though, will result in too many decisions made by one person. More democratic teams will develop more flexible work practices and collective decision making. The doctor may in fact be the least qualified in management and leadership skills within the team. Moreover, the reason why multidisciplinary teams can work so badly is frequently the scant regard paid to them by the medical profession. Non-medical leadership of the multidisciplinary team can work, particularly if the issue of responsibility for

decisions is satisfactorily addressed. A major DHSS document is clear that a consultant may not be held responsible for negligence on the part of others, simply because he is the "Responsible Medical Officer". It states he is not accountable like a military commander; "the multidisciplinary team has no commander in this sense"[9]. There is, however, a tendency to equate responsibility with out-of-hours accessibility, especially during a crisis.

It is important to remember that the key worker may not be the same person responsible for providing alternative care in the event of a crisis; e.g. the community mental health nurse (CMHN) may be the link with the elderly person at risk, but is unable to access directly residential care facilities should they be needed urgently.

For whoever dons the mantle of leader, skills in communication are a vital requirement, as is the ability to create a feeling of mutual trust and respect in order to maximize members' strengths and create compromise between individual members to fit in with overall team goals. Much of the motivation for the team will depend on the qualities of leadership. The creation of realistic goals gives a sense of purpose and a framework. Obviously, resource constraints are a major barrier to this process. It is important to distinguish the demands of budget holding from clinical management, and where the multidisciplinary leader is also the budget holder, the team members will need to learn the wider issues in the face of restrictions caused by tight fiscal control. They will need to feel the leader's commitment and sincerity in the care of their clients or patients.

Audit

The Department of Health encouraged medical audit as a means of improving service delivery and management[10]. Care of the elderly psychiatrically ill requires more complex assessment than pure medical audit, and the multidisciplinary team is in the key position to instigate clinical audit because of its potential for knocking down interprofessional barriers and prejudice. Multidisciplinary audit can be attempted if the process is viewed from a positive and non-defensive position. Good and bad practices in liaison will be easily revealed, particularly if the patients' and carers' views are included in outcome measures. The team should be in a constant state of evolution and be able to incorporate new ideas. This sense of objectivity and self-assessment will be created by a positive clinical audit programme and will itself become part of the quality of the successful team.

Morale

Clearly, morale is dependent on the key issues—leadership, communication, achievement of goals and self-assessment, described above. Other ingredients need adding to the recipe. Morale relies heavily on personal support and encouragement within the team. Through time, most team members experience stresses and problems, which may affect their judgement and possibly their self-esteem. This support may be available discreetly or offered more formally through staff groups and supervision. Whatever its form, its value is its ready accessibility and confidentiality.

The ability of the team members to see the funny side of a situation is often a vital component in the maintenance of morale. Involvement in non-clinical activities, such as fundraising or games matches against other units, may have positive effects on morale—even in defeat. In essence, it is important to create in team members a sense of personal value and ownership of their team. In the current climate of health service reorganization and cost–benefit assessment, the sharing of successes in patient treatment can contribute greatly to good morale.

FUTURE DEVELOPMENT OF THE MULTIDISCIPLINARY APPROACH

The introduction of goal-orientated multidisciplinary methods of treatment require changes in structures of healthcare organization[11]. Sadly, the move towards care management detailed in *Caring for People in the Next Decade and Beyond*[2] has not been complemented by sufficient funding to meet the requisite planning, training and research needs. Either the resources are not available to get multidisciplinary teams properly established, or there is insufficient funding to achieve even modest treatment goals. It is disputes over limited funding that can lead to the break-up of collaboration between agencies and effective teamwork.

Planning

The last decade has, however, seen an encouraging trend in the sophistication of expertise within the psychogeriatric team, producing greater quality of care of the elderly psychiatrically ill. The CMHN has developed roles in early case assessment and liaison with associated professionals. Because of the high profile in the locality, the CMHN has forged links with many agencies, e.g. district nurses, specialist housing, residential care facilities, and facilities for the treatment of alcoholism. Together with the increasingly skilled work with dementia sufferers, functionally ill patients and carers, the CMHN now brings to the multidisciplinary team a more vital and complex role. The social worker is still not given sufficient time to use her training in casework from the all too demanding accommodation-finding role. Historically, the champion of patients' rights, the social worker, may now access independent advocacy schemes. The roles of the occupational therapist and physiotherapist have been further strengthened by their involvement in community assessment liaison. The clinical psychologist finds much demand within the team, not only for assessment of areas of cognitive deficit in the patient, but also increasingly for the treatment of functional disorder, e.g. cognitive therapy and the evaluation of staff management methods and attitudes. There remains a paucity of training places in clinical psychology.

The shifting nature of the multidisciplinary team approach is further advanced by the recognition of the increasing role the voluntary sector can offer, both informally, using volunteers as befrienders of the patient, and more formally by such organizations as Age Concern and the Alzheimer's Disease Society, providing essential services such as day care. The role of the coordinator of such services can play an important part within the multidisciplinary team[12].

The expanding therapeutic team must recognize the problems that may arise when a new worker comes to fill a specific role carried out more generally by other workers, e.g. a social worker being appointed where previously much informal casework was conducted by the CMHN. Members of smaller teams may appear to have less distinct professional roles. Concentration on individual strengths, not weaknesses, will enable expansion of the team to take place.

Training

It is not clear that such growth in individual professional expertise in care of the elderly psychiatrically ill has been matched by the requisite training in multidisciplinary teamwork skills, particularly in undergraduate medical education. The General Medical Council, in its publication, *Teaching Tomorrow's Doctors*, has recognized this shortfall[13]. Attitudes and techniques in

cooperation with other disciplines will need to be explored in order to escape from the purely medical model of treatment.

Case studies have been described as being well suited for teaching, in an interesting and understandable way, the complexities in the field of geriatric medicine, where an increased degree of integration with other services is required[14]. This must also be true in geriatric psychiatry. By the careful selection of cases to illustrate psychological, medical and social issues, the trainee should be stimulated rather than confused. This is an ideal opportunity for multidisciplinary teaching, enabling the learner to understand the different professional roles. The aim should be to show that complex cases might be manageable by the establishment of treatment goals, even if they are necessarily limited. Cultural, ethical and legal issues can be shown to have an important influence on the equation. Teaching by the use of case studies can be a good focus for multidisciplinary learning for groups of trainees from different professional backgrounds.

Planned community visiting sessions with the CMHN or social worker are highly valued by undergraduates of all relevant professions at Southampton University Medical School.

Doctors in higher training to be consultants in the field of old age psychiatry demand experience in multidisciplinary teamwork and should have flexibility in their programmes to permit in-depth exploration of the roles of the different members of the team. A variety of multidisciplinary teams should be observed, including those in other psychogeriatric units.

Individual professional training must be mirrored by developments encompassing different professional groups. A training model has been devised to overcome the organizational isolation of agencies serving mutual elderly clients with mental health problems in Philadelphia[15]. Training issues were explored at a conference on interdisciplinary issues in mental health and ageing, where interprofessional cooperation was reaffirmed and strengthened[16]. There is a rising swell of workshops on collaborative care in the management of the elderly psychiatrically ill, much of it promoted by initiatives from the voluntary sector and much of it relevant to the training needs of the multidisciplinary team.

Research

Objective research in the workings of the multidisciplinary team has received little attention in the case of the elderly psychiatrically ill. A review of the role and effect of this teamwork in the management of delirium in dementia found insufficient data for the development of evidence-based guidelines[17]. A difficulty is that evaluation has been mainly restricted to descriptive terms using, for example, in-depth individual case studies. In this area in particular, clinical audit and operational research are almost indistinguishable. Outcome measures, however, using quantity and timing of liaison, do not measure the essential components of the workings of the team—the quality of the relationships and the ability to respond as a whole to the needs of the patient. Study is still required into the methods of evaluating the effect of the quality of these relationships, particularly within the field of old age psychiatry.

Community Care: the Background

Colin Godber

Moorgreen Hospital, Southampton, UK

The specialty of old age psychiatry in Britain grew out of the failure of orthodox, institutionally-based psychiatry to meet the needs of the growing number of elderly people with dementia. Its success stemmed from its proactive community-based approach, an emphasis on the support of family and other carers and the demonstration of the positive outcomes obtainable through better recognition and energetic treatment of much of the functional illness of old age[1]. Crucial to that approach and the effectiveness of the elderly mental health service itself has been the development of partnerships across health and social services, support to informal carers and the increasing range of care staff working directly with patients. Just as it has led the rest of psychiatry in assertive outreach, it has often taken over from the increasingly hospital-centred geriatric medicine as a catalyst and advocate for community care for older people. This chapter will look at some of the components and contributors to that care, as well as some of the wider organizational and political factors that have influenced it.

PRIMARY HEALTH CARE

General practice has always been the cornerstone of the National Health Service (NHS) in Britain, providing continuity of individual and family care and acting as gatekeeper to secondary care. Aggregation into group practices paved the way to the establishment of the primary healthcare team (PHCT), with its core membership of general practitioner (GP), practice nurse, district nurse and health visitor, and later a looser attachment or sessional input from community mental health nurses (CMHNs), podiatrists, physiotherapists, counsellors and specialists from secondary care. The PHCT provides the bulk of domiciliary health care and surveillance of those at risk and the main day-to-day link with social services, housing and other local agencies supporting disabled people in their homes.

With the aim of strengthening the locality and primary care focus of the NHS, the incoming Labour government[2] has aggregated groups of PHCTs covering "natural" localities of 50–150 000 population into primary care groups (PCGs). Healthcare budgets for these localities have been devolved to PCGs, who are responsible for increasing the equity and quality of primary care within local populations, for assessing their health needs and for commissioning secondary care services. There is also the option/expectation that PCGs will progress to fuller autonomy as primary care trusts (PCTs). These will be empowered to take over the management, for instance, of community hospitals and appropriate secondary care services and will be expected to develop closer partnerships with local social services. It is likely, therefore, that PCTs will take on a much more comprehensive role in the provision of community care within the Health Service. Parallel legislation[3,4] will also facilitate partnership with local authority services by enabling them to pool and ring-fence budgets to promote joint services, long advocated by proponents of community care.

INFORMAL CARERS

By far the largest contribution to domiciliary care, particularly for those with dementia, is of course that of family members and friends. The main carer is usually a spouse or partner, although care by daughters, sons and daughters-in-law remains substantial, despite greater geographical mobility, changing employment patterns and the steadily falling ratio of middle-aged to elderly people. Input from neighbours can also be vital and some areas have well-developed community networks. The House of Commons Social Services Select Committee[5] estimated the "replacement cost" of informal carers for the disabled in Britain (over three-quarters of a million "on their feet" for more than 50 h week) as well above the total expenditure on all statutory care. The government recently acknowledged the importance of carers and the load they carry and announced a strategy to ensure that their needs will be properly assessed and that they become eligible for extra financial support[6].

BACK-UP FROM GERIATRIC PSYCHIATRY

Partnership with family carers is fundamental to the practice of old age psychiatry, especially in the context of dementia. Initial assessment should include the extent of informal care, the health and attitude of the carers and the prospects for sustaining such care in the future, given adequate help. Carers need the support of a key worker with a good knowledge of the "system" who can help them access appropriate services and allowances and the practical and psychological value of carer support groups. Important aspects of that key working are its continuity, attention to the health and morale of the carers and prompt arrangement of further assessment, intervention and respite when the need arises.

For those with psychiatric illness, and particularly dementia, the key worker will usually be the CMHN, working closely with colleagues in primary health care and social services teams. CMHNs also have an important support and educational role, with the increasing number of untrained voluntary and paid carers working with patients in their homes, day centres and residential care. They will also draw on the range of skills and

resources of the specialist team itself for further assessment, treatment, respite or crisis intervention. A great deal of the work of the elderly mental health service takes place in the patient's home. Ours, for example (catering for an elderly population of 60 000), has 20 CMHNs, all with large case-loads and between them clocking up about 20 000 patient contacts a year. This is complemented by outreach from other members of the service (e.g. 8000 medical community contacts), two day hospitals and deployment of staff to support day centres specializing in the care of the elderly patients with mental health problems. An original bed complement of 250 (mainly long-stay) has reconfigured to 40 continuing-care and 90 short-stay beds, 35 of the latter for functional illness. This has necessitated extensive outreach and support to residential and nursing homes but has released funds to redeploy into community developments, such as the establishment[7] of a sitting service to offer home respite to carers for demented patients. This has now diversified into other areas of community support for elderly people with mental health problems as a thriving provider in the new mixed economy of community care.

SOCIAL CARE IN THE COMMUNITY

Progress in community care in Britain has been hampered by the very different way in which health and social services are organized and financed and the frequent lack of co-terminosity in their local boundaries. The NHS is funded from taxation and is predominantly free at the point of delivery. It has strong central direction and is coordinated locally by (unelected) district health authorities. Social and housing services are run by (elected) local authorities, which receive block allocations from central government but also have to raise much of their revenue through local taxation and by means-tested charging of services to clients. Local authorities were traditionally the main providers of domiciliary and residential support for disabled people.

The 1970s saw many initiatives in specialized supported housing for older people[8–10] and in individualized and sometimes intensive domiciliary services to support, in their own homes, frail elderly people who might otherwise have required residential care. Evaluation of these and subsequent projects usually showed them to be valued by clients and generally cost-effective at low and moderate levels of disability, but decreasingly so (and at times very expensive) for those with heavier dependency[10,11]. Because they generally rely on intermittent carer input or on the client summoning assistance, they tend to be less effective for patients with advancing dementia than for those with a purely physical disability.

Generalization of these initiatives in community care was seriously hampered by the economic problems of the 1970s and early 1980s. The incoming Thatcher government found things reaching crisis point but was unwilling to give the necessary support to local authorities to expand domiciliary based care. Instead, it changed the regulations governing social security benefits[12] to allow these to be used to pay fees in private residential and nursing homes, with no provision for needs assessment. This led to a huge expansion (from £10 million to over £1 billion a year during the 1980s) in this sector, but none in domiciliary provision, which was not eligible for this source of funding. This wasteful and retrograde trend was castigated by the Audit Commission[13], which drew attention to the contrasting effectiveness and popularity of the Kent Community Care scheme[14,15]. This had been using care management to assess the needs of frail elderly people in the community and to put together packages of domiciliary care, drawing on a range of neighbourhood resources. This was enabling many people who would otherwise have needed residential care to remain in their own homes, despite a budget ceiling well below the cost of the residential placement.

To establish a transition to this model, the Audit Commission proposed a ring-fencing of all public expenditure on community and institutionally-based continuing care (including all residential, nursing home and NHS continuing care) to be administered by a single district care agency on a care management basis. These proposals were endorsed by the government's management guru[16], who also stressed the need to ring-fence the budgets for all continuing care and to ensure adequate transitional funding to secure ample early investment in domiciliary-based options. The resulting White Paper[17] unfortunately ignored these two crucial points. The result gave Social Services departments the responsibility for care management (including the purchase of long-term nursing home care) but without arrangements for any transfer of funds released within the NHS if it closed equivalent continuing-care beds.

Implementation of the Act since 1993 has therefore brought about a modified resurgence of community care for older people in Britain. Social services departments were encouraged to focus on the assessment and care management functions and to stimulate a mixed economy of domiciliary care providers, from whom they purchase packages tailored to the needs of clients. It is very gratifying to see one's patients getting individualized support packages, combining informal, social and healthcare elements and often assembled at short notice in the event of a crisis. Aware of the growing pressure on acute hospital beds, some health and social services departments have also collaborated to develop domiciliary and intermediate care options to reduce the need for hospital admission and facilitate early discharge[18]. The advent of PCGs should certainly stimulate that sort of approach. Unfortunately, because the means-testing rules make residential care cheaper for social services than the domiciliary equivalent for anyone with moderate care needs, the cost ceiling applied by most departments to domiciliary packages for individual clients is a long way below the level of residential home fees. This rules out such care for many people for whom it would otherwise have continued to be cost-effective, particularly those with dementia.

POLITICAL AND ECONOMIC FACTORS

Lack of investment has been the main cause of our slow progress with community care for older people in Britain. The politicians have generally been seduced into thinking that it is a cheap option, but at times of economic hardship domiciliary provision has always been the first target for cuts. In the 1980s spending on care of the elderly increased greatly but in the wrong direction and it is taking a long time for the pendulum to swing back. The separate organization and funding of health and social care have created perverse incentives, which have been exploited to preserve an inadequately funded NHS by narrowing its focus to the care of acute illness. This constriction of the range of free NHS care has led to artificial and increasingly absurd demarcations between health and social care, which undermines efficient and effective partnership and has thrown an increasing share of the cost onto patients themselves. Failure to ring-fence the NHS continuing care within the community care budget has allowed the closure of 60 000 beds since 1990 (with savings redeployed to support other NHS priorities), while social services have had to pick up the load with an increase in their nursing home purchasing from 100 000 to 180 000 beds—a cost shift to social services and (through means testing) to patients and families of over £300 million a year. Not surprisingly, this has encroached on investment in domiciliary care, which only increased by 56% in the first 5 years of implementation of the community care legislation[18].

This shrinkage in the role of the NHS in continuing care and rehabilitation and the barrier to effective services created by the artificial distinction between health and social care[19] has been widely criticized[18,20,21]. There is growing consensus that things will only get properly "joined up" when the funding rules for health and social care are harmonized and the nettle of the cost of our ageing population is properly grasped by the politicians. The Royal Commission[23] set up by the government recommended that all care (as opposed to board and lodging and general living) costs should be publicly funded from general taxation, eliciting little response as yet from a government still wedded to reducing taxation and maintaining means testing. The earlier Joseph Rowntree Enquiry[22] reached similar conclusions on the care costs but favoured a hypothecated, prospective, compulsory health/social care insurance levied on payrolls as a way of enabling each generation to fund its own care in old age. If the government finally accepts one or other of these options, the millennium could usher in an exciting new phase in community care.

Health Care of the Elderly: the Nottingham Model

Tom Arie

University of Nottingham, UK

The Nottingham University Department of Health Care of the Elderly was designed as a collaboration in which physicians, psychiatrists, gerontologists and other health workers are equal partners. It is neither a department of psychiatry with geriatricians on its staff, nor vice versa: it is an integrated joint enterprise. It was the model for 20 years. Following the retirement of the foundation professor, the university restructured the Department but the service ethos continues, as does the joint teaching programme. Described here is the Joint Department as it was, and as it became well known, from 1977 to 1997.

Diagrams may put things best. Figure 1 shows the structure, and makes the important point that although the department is unified, its services are differentiated. Physicians do medical work, psychiatrists psychiatry. There is cross-training, and above all constant formal and informal collaboration and support, both in the hospital and in assessing and keeping people going at home.

The aim is to make easily available what patients need. Thus, a patient of the psychiatric service has as easy access to physicians and their facilities as if he/she were their patient, and vice versa. In this way it is possible to offer responses that match the pattern of morbidity characteristic of the very old, namely that it is mixed and often unpredictably changeable. There are no demarcation disputes, and there is no waiting list. Things were very different when the department was established in 1977.

INTEGRATION

The services are based in two general teaching hospitals. In University Hospital the professorial unit has a medical and a psychiatric ward side-by-side. There are close links with the rest of the health specialties and professions, both inside and outside the hospital. For instance, trainees rotate from general medicine,

Health Care of the Elderly: the Nottingham Model

Tom Arie
University of Nottingham, UK

The Nottingham University Department of Health Care of the Elderly was designed as a collaboration in which physicians, psychiatrists, gerontologists and other health workers are equal partners. It is neither a department of psychiatry with geriatricians on its staff, nor vice versa: it is an integrated joint enterprise. It was the model for 20 years. Following the retirement of the foundation professor, the university restructured the Department but the service ethos continues, as does the joint teaching programme. Described here is the Joint Department as it was, and as it became well known, from 1977 to 1997.

Diagrams may put things best. Figure 1 shows the structure, and makes the important point that although the department is unified, its services are differentiated. Physicians do medical work, psychiatrists psychiatry. There is cross-training, and above all constant formal and informal collaboration and support, both in the hospital and in assessing and keeping people going at home.

The aim is to make easily available what patients need. Thus, a patient of the psychiatric service has as easy access to physicians and their facilities as if he/she were their patient, and vice versa. In this way it is possible to offer responses that match the pattern of morbidity characteristic of the very old, namely that it is mixed and often unpredictably changeable. There are no demarcation disputes, and there is no waiting list. Things were very different when the department was established in 1977.

INTEGRATION

The services are based in two general teaching hospitals. In University Hospital the professorial unit has a medical and a psychiatric ward side-by-side. There are close links with the rest of the health specialties and professions, both inside and outside the hospital. For instance, trainees rotate from general medicine,

psychiatry and general practice (Figure 2), and there is pairing with medical and surgical firms. The department is embedded in the local medical community, and particularly values its links with the parent disciplines of medicine and psychiatry and its closeness to primary care. All referrals to the psychiatric side of the department are initially seen at home by a senior psychiatrist, usually together with a medical student, and any other team members or community staff who are involved and able to be present, and if possible the family doctor is present too. In practice, most visits are by psychiatrist and medical student. On the medical side of the department a home assessment service is freely available, but the majority of patients are seen in the clinic, or admitted as emergencies. Community nurses, working outwards from the hospital, are part of both the medical and psychiatric services.

EDUCATION AND RESEARCH

All Nottingham medical students spend a month full-time in the department. Teaching is a joint effort between all staff, of whatever specialty, medical and non-medical. The course comprises: a clinical clerkship, inside and outside the hospital; a planned course of teaching; and a personal project under supervision. With about 150 students a year, there is a heavy teaching load. The course is well received and many students come back as postgraduate trainees. Rotating trainees come to acquire better skills (and, we hope, greater job satisfaction) in dealing with old people in whatever field they decide eventually to work. Only the senior registrars are being trained to become specialists in old age.

Research thrives on collaboration and transcends boundaries of departments: we have long been collaborating with other departments, and within a mixed department research collaboration comes easily. Major projects include longitudinal studies of well-being of old people at home—the Activity and Ageing Study—and participation in the Medical Research Council study of Cognitive Function and Ageing (CFAS). Most projects have involved staff from both of the main branches of the department.

CONCLUSION

What has been called "the Nottingham Model" works well, and is a satisfying way in which to work. There have naturally been day-to-day problems, some general, others parochial, but none that have divided the department along specialty lines. Above all, patients do not fall between stools and bucks do not get passed.

The Development of Day Hospitals and Day Care

Rosie Jenkins and D. J. Jolley
Penn Hospital, Wolverhampton, UK

ORIGINS

Day hospitals are said to be among the few notable creations that psychiatry has given to medicine[1]. The concept that older people could be given treatment, rehabilitation and care without resorting to "inpatient" status within hospitals or related "institutions" was accepted enthusiastically in the UK from the late 1960s. "Partial hospitalization" (usually day hospital care, but sometimes night care, relief admission programmes, rotating care or shared bed schemes), linked to active community services, has been a feature of the services provided for the elderly, not only by psychiatrists but also geriatric physicians. Non-medical agencies, such as social services departments and voluntary bodies, have also participated. Interestingly, and perhaps significantly, the private sector has been much less enthusiastic for partial hospitalization schemes. This appears to be true for other countries.

ATTRACTIONS

The attractions of day care are most obvious for the patient, who is enabled to maintain his/her home routines and contact with his/her supports, whilst taking advantage of professional expertise in treatment during certain parts of the day. Family members or carers may have mixed perceptions: their burden of anxiety and responsibility for the ill or disabled patient is relieved only episodically and only in part; yet many are pleased with this opportunity to continue to contribute to care and for therapy with the guidance of professionals. The resources of the day hospital add to the resources of family life[2]. For the health care agency (the National Health Service), day hospital development has been attractive for its flexibility and apparent cheapness. It may not, however, represent a cheap option. Its importance to health care systems lies in its influence on the effectiveness and smooth running of inpatient and other domiciliary or extramural and partial hospitalization projects. These are increasingly likely to be cooperative ventures with other care-providing agencies, such as social services[3].

SPREAD WITHIN THE UK

At the end of the 1960s, the Department of Health was prompted by a pressing need to review the services it was providing to the increasing numbers of older people suffering from dementia and other major psychiatric disorders. This revealed a woeful situation, with relatively few beds, badly supported and in inappropriate locations, frequently operating with waiting lists, that saw patients dying before admission[4].

A review of provision based on the 1971 census was to establish the baseline for inpatient services[5] and health authorities were encouraged to create day hospital places in equal numbers, often starting from zero[6]. As little guidance was given in respect of the development of these day hospitals, a wide variety of interpretations arose from practitioners and planners trying to produce the best possible facilities. Between 1976–1986 the total number of day hospital places for the mentally ill increased by 50%. Provision for the elderly ranged from 129 places/10 000 in East Anglia to 693/10 000 in the North West[7]. Wide variations persist between areas in respect of day hospital places available to the elderly populations served, and the Royal College of Psychiatry's recommendations of one place for every 500 (or fewer) of the elderly population[8] is not yet seen everywhere, for a variety of financial and other reasons.

STRUCTURES

The cheapest option for developing day hospital provision was to place the facility in a disused part of a mental hospital, and risk the deficiencies of the parent hospital transferring to the new unit. Interestingly, the effect tended to be positive, for both the new venture and the existing facilities for this patient group, and illustrates a potential of such care—the link with inpatient services benefits the day care unit, its attenders and their carers, and encourages wards to provide care more relevant to population needs. Alternatively, developments took advantage of existing premises, designed for other purposes but away from the mental hospital and often in the area to be served[9]. "Travelling" day hospitals used a network of such premises, staff moving between the locations to provide care on different days[10], a useful system for rural communities.

The ideal would be purpose-built units, probably on health authority land and sited conveniently in the catchment area. No bed provision is required and staff are not employed when the unit is closed. These developments can also create a positive image for a vital, if unfashionable, service by raising its community profile.

Such "stand-alone" day hospitals run the risk of being seen as distant from the inpatient services, and may detract from the reputation of the latter, especially as they are often seen as more thrusting and challenging. This can hinder cooperative efforts, such as when a patient requires a period of short-term, rotating or prolonged inpatient care[11]. Probably the best model places day hospital and inpatient facilities within the same unit, with several

such units of modest size at strategic sites throughout the community to be served (Figure 124.1).

FUNCTIONS

A day hospital may aim to provide one or more of a series of care options for the elderly attender. It may offer assessment and treatment otherwise requiring admission, facilitate early discharge from inpatient care, provide rehabilitation, or help attenders deskilled or disabled by long experience of illness. Additionally, it may provide continuing support for patients with established disabilities (with or without a known vulnerability to major decompensations), arguably in itself a rehabilitative regimen attempting to prevent further deterioration and also providing carer support. In practice, many day hospitals perform mixed functions and may not have formally determined aims. The experience of others can serve to inform the process of defining such objectives.

Bergmann *et al.*'s[12] general hospital-based day hospital in Newcastle functioned as an assessment and early treatment unit, without initial home visits and very much in the manner of a tertiary referral facility for other teams working out of existing mental hospitals. Alongside was a small ward with a similar function, and the team also undertook liaison work—probably representing the best use for this day hospital within the city's then mental health provision. Even so, and despite a highly skilled and single-minded team, the successful pursuit of "assessment only" is difficult to sustain. Bergmann reported that the day hospital's advice, after assessment, was taken or acted upon in disappointingly few cases. Whitehead[13] also stressed the assessment and treatment potential of the day hospital, designating it perhaps the key element in a community-orientated old age service. He was, however, providing a comprehensive range of services within one team, with home-based assessment and treatment available before a decision regarding the use of the day hospital or a small inpatient unit. His unsatisfactory experience of poor-quality mental hospital wards determined his philosophy that recourse to inpatient care would be taken for very few patients.

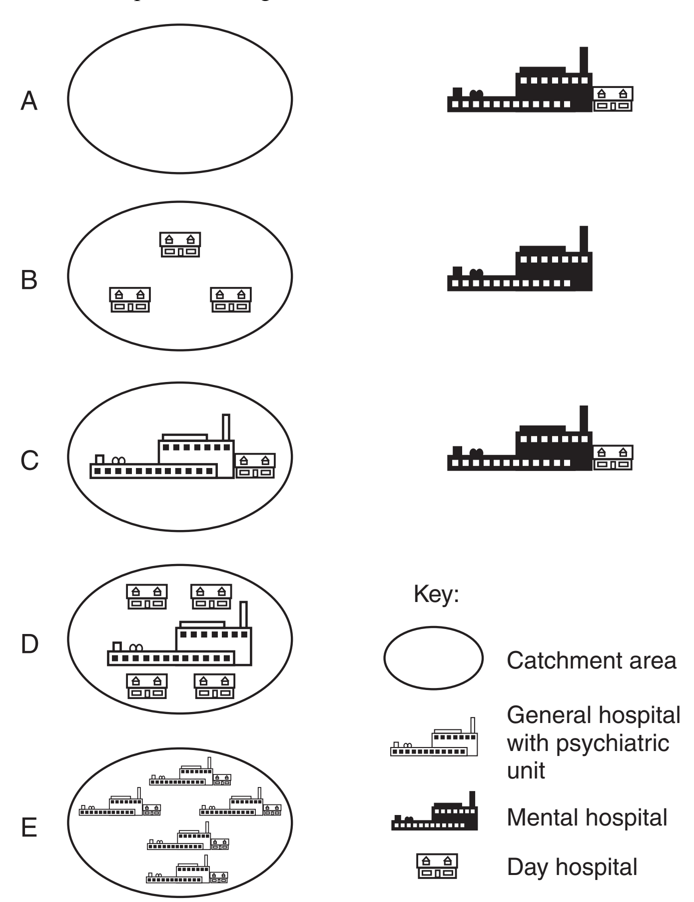

Figure 124.1 Models of day hospital provision. (A) Large mental hospital geographically distant from catchment area served, starting day care on site. (B) Mental hospital supported by stand-alone day hospitals within catchment area. (C) Mental hospital beginning to give way to district hospital unit, both sites with inpatient and day hospital facilities. (D) General hospital with psychiatric unit supported by stand-alone day hospitals. (E) General hospital with day hospital unit and supported by several units within the catchment area, each offering inpatient and day hospital care.

Such models of care are attractive, but were influenced by other factors: for Bergmann, longer-term care was available elsewhere, and Whitehead had a supportive nursing home sector sympathetic to his vision[14]. Other authors have been uncomfortable with day hospitals that appear to function mostly to delay entry into long-term care[15,16]: however, for some individuals and their carers, this may be the very help they want, and should be evaluated in this light.

Arie[17] identified two groups of patients benefiting from long-term day hospital attendance: dementia sufferers living with carers wanting them to remain at home, but who needed help and some respite from the carer role; and patients with relapsing illnesses complicated by persisting "neurotic" symptoms when well. The latter were almost all women living alone. Others working in well-sited and well-equipped day hospitals have confirmed these images of the successful long-term patient. Here, the male:female ratio of dementia sufferers was often equal, and some attended from rest homes. There was also an intermediate group, suffering from mood disorder or neurotic symptoms associated with quite severe physical disability (from stroke, parkinsonism, arthritis, chest or heart conditions), having nursing needs as great as those of dementia sufferers, but with psychological needs akin to other "functional" patients[11].

The "mix" of day hospital attenders can be crucial. Individuals severely damaged by dementia benefit from simple, structured and repetitive activities that are unhelpful and unrewarding to their cognitively intact peers. Where dementia has caused a decline in physical abilities, basic group physiotherapy techniques can be beneficial, whereas other patients with complex physical and psychological needs may only thrive with individually tailored personal care interventions. Mixing patients with widely differing cognitive abilities can be unacceptable to both the better and the less able. Potential tensions can be reduced by using different areas of the unit for different purposes, or by having day-specific activities. Where several local day hospitals coexist, they may develop specialized roles[11].

Most practitioners with day hospitals available for their patients are enthusiastic about their potential, but there have been few robust evaluations of the efficacy of day hospitals. Philpott's review[18] cautiously concluded that day hospitals remained experimental care delivery systems. Creed and colleagues, after reviewing studies of day hospital care[19], evaluated day hospital activities in the north-west of England[20]. They confirmed that day hospitals are able to provide alternative care for many patients but that not all such facilities can, or want to, provide the same service[21]. Longer periods of treatment may be offset by greater efficacy in preventing relapse and maintaining independence[22].

The costs of day hospital care are probably lower than those for inpatient care. MacDonald *et al.*[23] undertook an extensive study of outcomes in matched groups of elderly people with mild to moderate dementia in four care settings in London. They found no significant differences in mortality or in changes on dementia scores. They concluded that non-hospital day centres offered the best value.

Panella *et al.*[24] found that only 69 of 314 elderly demented patients likely to benefit from day hospital programmes in Burke, USA, took advantage of them. For these, the costs were estimated to be considerably lower than nursing home care and the programme was acceptable to patients and carers. Zeeli and Isaacs[25], despite describing a geriatric day hospital where 75% of attenders' time was spent in active therapy and transport problems were non-existent, still showed only half the patients completing planned treatment. Only one-third achieved staff-determined objectives or felt improved by 3 months.

Transport problems, along with changes in health or social circumstances, were often associated with costly lost days of care in the comprehensive review performed by Eagle *et al.*[26], but the work confirmed the positive effects of day hospital care on the physical and emotional health of elderly attenders.

The Audit Commission[27] has confirmed the expense of day care when linked to domiciliary support services to the moderately disabled—it can exceed the cost of residential care, and the cost of informal care is all but impossible to calculate. This does not mean it is not preferable to other forms of care.

Donaldson, Wright and Maynard[28] emphasized the need to consider several measures when assessing day hospital care. These included the costs of all services used over a designated period, with clinical, social and psychological measures at set intervals related to treatment and follow-up, and carer and patient satisfaction scores. As yet, few if any studies have examined all these aspects of care, although a work in progress by Read and her colleagues in a joint day care/day hospital project in Wolverhampton is designed along very similar lines to those suggested by Donaldson's team[29]. This evaluation is also attempting to place such care in context with other care and services available. More comprehensive assessments of the efficacy of all available complementary facilities individually and within systems are necessary to tease out the particular effects of day hospitals. These would include measures of the morale and self-image of professional carers in the sectors and their views and attitudes towards other complementary services, patients and their carers. These considerations reflect the complexities of the processes of care delivery to the elderly mentally ill, and the relationships between "consumers" and "providers".

CONCLUSION

Day hospitals for the elderly mentally ill have become established services, especially within the UK. There is little reason to doubt that they fulfil a useful and acceptable function. Providing something of this nature has both energized and encouraged developments in many areas. Refinements of practice occur over time as individual day hospitals modify what they do in the context of a changing awareness of their own potentials and weaknesses, and in relation to changes in other services available to the potential client or patient group. Formal research evaluations continue and may better inform such evolutionary developments and future planning. It remains important to be aware of the limitations of such evaluative research and it would be quite wrong to stop good ideas being put into practice on the "quasi-scientific" basis that "its cost-effectiveness cannot be demonstrated".

Day Care

John M. Eagles and Jill Warrington
Royal Cornhill Hospital, Aberdeen, UK

The first psychiatric day hospitals in the UK opened in the late 1940s and their numbers have continued to grow over the five subsequent decades. In geriatric psychiatry, as in geriatric medicine, the proliferation of day care facilities came rather later, with large expansions of such services since the 1960s. A similar proliferation of day care facilities for the elderly with psychiatric difficulties has occurred in other parts of the world[1–3], with parallel expansions in both the health and social care sectors[4]. Since their inception, day care facilities, in all their many and disparate forms, have come to be viewed as essential components of most comprehensive old age psychiatry services. This chapter will seek to follow a brief description of day care facilities with a discussion of their aims and effectiveness, concluding with some current issues and possible future directions for day care services.

MODELS OF DAY CARE

Models of day care for the elderly mentally ill are extremely diverse. Indeed, given the relative lack of critical evaluation of such services, this is perhaps to be expected. This diversity is enhanced by the range of bodies funding and running day care services, including local authorities, the health service, voluntary agencies and the private sector.

Day hospitals and day centres are often described as distinctly differing facilities (as they will be in this chapter for the sake of clarity), although in reality the two types of facility more probably form part of a continuum. Day hospitals tend to be funded solely through health service budgets and to be staffed by health service professionals. Day hospitals will often be linked geographically with a hospital site and will thus have access to a full range of physical treatment and investigative facilities. The programmes at day hospitals are often intensive[5], with reality orientation, formalized social interaction, occupational therapy, physical activities and frequent meetings with the patients' families. Day centres, by contrast, are funded more usually by local authorities and/or voluntary agencies, and have a much lower proportion of health service professionals on their staff. Day centres are optimally sited in the community, close to the patient's home. The programmes at day centres tend to be less intensive and "medicalized", with greater emphasis on informal socialization and diversionary activities. Almost self-evidently, day centres are significantly cheaper to run than are day hospitals.

There is debate as to the optimal "mix" of patients/clients in day care facilities. Most day hospitals do mix the demented and the functionally ill elderly, although the latter group would usually form only 10–20% of the total. Since the first day hospitals were established, the numbers of functionally ill patients have probably declined, not through explicit policy decisions but as a result of increasing pressure from the growing number of demented elderly patients[6]. Some regions tend to incorporate the functionally ill elderly into general adult day hospitals, feeling that this affords such patients an environment that can be more accurately tailored to their needs. Chodosh *et al.*[7] describe a day care programme that mixes physically infirm with demented patients, but these authors reflect that their mentally infirm attenders would probably be better suited to a separate programme, in view of their shortened attention spans. In areas of low population density, taking services out to the patients, through travelling day hospitals, can be a very useful innovation[8,9]. In more rural areas, especially since underutilization of expensive custom-built facilities can have an adverse influence upon cost-effectiveness[10], it may be appropriate to integrate demented patients requiring day care into small community-based inpatient units[11].

AIMS OF DAY CARE

While it is fair to say that there is a general lack of clarity and agreement as to the aims of day care for the elderly, certain themes would be common to most patients in most settings. These would include relief from loneliness and boredom and the provision of stimulation and social support[12], while the aims of day hospitals will usually be broader and more ambitious.

As noted above, the substantial majority of elderly day hospital attenders suffer primarily from dementing illness. Most day hospitals, therefore, are geared more towards the needs of the demented than of the functionally ill elderly, whose day care requirements have thus received rather less attention. Cited roles of day hospitals for the functionally ill include assessment, continuation of treatment after hospital care, monitoring and encouraging compliance with medication, and focused group activities dealing with issues such as bereavement.

For the demented elderly, many aims of day hospital care have been described and these would include: assessment, providing an alternative to institutional care, treatment of cognitive and non-cognitive symptoms of dementia, relieving stress on caregivers, determining whether institutional care is required and what the optimal form thereof will comprise, easing the transition from home to institutional care, shortening hospital stays, acting as centres of expertise from which skills can be "exported", enhancing the morale of old age staff who rotate through day hospitals, and providing a focus for liaison with other care providers. The issue of whether these aims are effectively fulfilled will be discussed below.

It may sometimes be the case that the role of a day care facility is more reactive than proactive, and one pragmatic view is that the shape of day care develops partly to plug gaps in local services[13]. It may be worth noting also that the literature about the aims and benefits of day care is written almost exclusively by health care professionals about patients; certainly among younger patient groups, the most valued aspects of day care may not accord at all closely with those that might be highlighted by staff[14].

EFFECTIVENESS OF DAY CARE

There has been no evaluative research on the effectiveness of day care for the functionally ill elderly. If one can validly extrapolate from findings in younger patients, then compliance with medication can be enhanced by focused interventions with day hospital attenders[15]. Similarly, extending findings from the demented elderly might suggest that the often very stressful activity of caring for a depressed or psychotic relative would be relieved by the patient entering day care.

While it remains an under-researched area, there has been more evaluation of the effects of day care attendance among the demented elderly, although many of the hypothesized functions of day care have not been meaningfully scrutinized. For example, while many old age services regard assessment as a pivotal role of their day hospitals[9,16,17], another view is that this can be conducted just as well as an outpatient and/or in the patient's home[10]. There are no data to support either standpoint.

Reports of specific cognitive or non-cognitive benefits of day care among demented patients have not been consistent or confirmed, and tend to be based on anecdote[18]. Where ratings of change are made by carers, then such ratings may be influenced by improvements in the carers' well-being as a result of their dependants' day care attendance. If day care is indeed specifically beneficial to patients, then the improvements may be more subtle than can be measured with existing rating measures, and Donaghy[19] has noted that a validated quality of life measure for the demented elderly would constitute a significant advance. It is perhaps noteworthy that professionals now working with the demented elderly predict that day care would enhance their own quality of life should they develop dementia[20].

While day hospitals developed largely as an alleged alternative to long-term inpatient or other institutional care,[17] this hypothesized role may be outdated and there is little evidence that they fulfil this function. Patients admitted into long-stay care following day hospital attendance have been found to be no more disabled, cognitively or behaviourally, than those who had no experience of day care[21], suggesting that there was no delay in institutionalization. New day care facilities in an area do not appear to change the requirements for long-stay care[16]. It may be, however, that day care can shorten stays in acute inpatient facilities by acting as something of a ''half-way house'' between hospital and home while community links are re-established[17]. Mintzer *et al.*[22] in South Carolina, found that there was equal improvement in the agitation of demented patients who had a short admission followed by home assessment plus ''partial hospitalization'' and those who experienced a lengthier hospital stay.

The strongest evidence for the effectiveness of day care is in improving the well-being of carers. Earlier studies, such as that by Gilleard[23], tended to be naturalistic but demonstrated improvements in the psychological well-being of carers after their dependant commenced day care attendance. These improvements were not related to changes in the problems presented by their dependant and seemed to derive, therefore, from ''time out'' from the stresses of the care-giving role. More recently, quite well-designed controlled studies have been conducted. In Australia, Wells *et al.*[2] conducted a ''before and after'' day care comparison of supporters, and also a comparison of supporters receiving and those waiting for day care. They found no differences in caregivers' well-being but reflected that the average period of relief (11.9 hours/week) may have been insufficient to confer benefits. In a recent large study, Zarit *et al.*[24] found that supporters of demented day care attenders (minimum of 2 days/week) felt less overloaded, strained, depressed and angry than did supporters whose dependant had no access to day care. The issue of what the ''effective dose'' of day care might be to enhance carers' well-being remains a fairly open question[18].

COST-EFFECTIVENESS OF DAY CARE

Given the relative dearth of evaluative studies on the effectiveness of day care, it is unsurprising that cost-effectiveness is also an understudied area. With regard to the dementing elderly, the Scottish Chief Scientist Working Party[25] concluded, in 1988, that ''the available research indicates that virtually nothing is known about the economics of day hospitals'', and since then little useful information has accrued[18]. The study by Mintzer *et al.*[22] mentioned above, did conclude that their use of ''partial hospitalization'' was clearly a cost-effective method of instigating and continuing treatment for agitated patients with dementia. In Sweden, Wimo *et al.*[3] compared 55 demented patients in day care with 45 waiting list controls and noted a statistically non-significant trend suggesting that day care may be more cost-effective than other types of service provision. In their review of 16 adult day centres across the USA, Reifler *et al.*[26] considered that one of the keys to cost efficiency was improved utilization, which related to meeting ''customer demands'', such as the need for transport and opening for a longer day between 7.30 a.m. and 6 p.m. Perhaps specific to health and social care systems in the USA, these authors make other suggestions as to how the financial viability of day care facilities can be enhanced.

DAY HOSPITALS OR DAY CENTRES?

Studies of demented attenders at day hospitals and at day centres tend to find that those at the former are rather more demented and more behaviourally disturbed, but that the similarities are more striking than the differences between the two groups of attenders[27–29]. This gives rise to the view that a proportion of demented attenders at day hospitals could have their needs met more cost-effectively at day centres, as has also been suggested for younger adults attending day hospitals in north-west England[30]. This view is strengthened by findings that supporters of the demented elderly attending day hospitals do not derive more psychological benefit than those whose dependant goes to a day centre[28,31,32]. Comparisons against day centres of other suggested functions of day hospitals, such as assessment and treatment of non-cognitive symptoms, have not been conducted. Furthermore, no randomized trials of day hospital vs. day centre care have been conducted among demented subjects, and while such studies would be difficult to conduct, they are likely to be feasible, given that they are possible among the physically disabled elderly[33].

PROBLEMS AND ISSUES IN DAY CARE

As has been indicated above, there is a considerable need to address the issue of the effectiveness and the cost-effectiveness of different day care programmes and of the specific components of these programmes, even although this is an undeniably complex task. Other common issues in day care will be touched upon below.

Within busy day care settings, it is often difficult to ensure continuity of care for those attending. This potential problem can be ameliorated by the appointment for each client of a "key worker", whose role is to coordinate the programme for that individual. This process can be facilitated by a "problem list", with a corresponding list of proposed action for each problem area. The key worker can also play a crucial role in helping to coordinate other community services: Peach and Pathy[34] have shown that day hospital attendance can be coupled with a reduction in other social supports without deleterious effects upon the patient. The key worker can also maintain links with other members of the multidisciplinary team who are involved in the patient's care.

Levin *et al.*[31] have highlighted the underprovision of day care facilities, with a minority of demented individuals in the community having access to such facilities. While selection of demented patients for day care seems somewhat arbitrary[28], it might be considered reasonable to prioritize day hospital places for those with complex needs, where assessment, problem identification and management may lead to improvement in the patient or allow for easier caregiving. Day hospital assessment may be especially helpful in the assessment of patients who live alone, where adequate information cannot be gathered through home or outpatient assessment. In the absence of complex needs and where the main aims are stimulation for the patient and respite for the caregiver, then lower-cost day centre care may suffice. Linked to this issue is the question of how many days per week a patient should attend. Research is required into whether day care should seek to provide a lot of respite for a few selected carers or a little respite for many more carers.

The vast majority of day care programmes operate during normal working hours. It is likely that supporters would be even more appreciative of time for themselves in the evenings and at weekends[31,35].

SUMMARY AND FUTURE DIRECTIONS

Few mental health practitioners would dispute that "day care, whatever its source, is a key component of comprehensive services to elderly persons and their families"[31]. However, in this increasingly cost-conscious age, such an assertion will not ensure continuation and expansion of day care services without adequate evaluation of their efficacy and cost-effectiveness. Day care services will probably become progressively aligned with other community resources for the elderly and it will surely be helpful if there is increased integration of health service day hospitals and social services day centres. Unless benefit can be demonstrated from the intensive involvement of mental health professionals, particularly nursing staff, then it is likely that there will be a progressive move toward staffing day care programmes predominantly with (cheaper) untrained personnel. In addition to studies of efficacy, there is a need to investigate further the selection of patients for day care, the most appropriate hours for programmes to operate and the optimal degree of respite that should be offered to supporters of the demented elderly.

New Technology and the Care of Cognitively Impaired Older People

Andrew J. Sixsmith
University of Liverpool, UK

Recent years have seen a rapid growth in research and development of new technologies to improve services and enhance the independence and quality of life of older people. The actual and potential role of new technologies has been recognized by the UK Royal Commission on Long-term Care[1], by the European Commission in their COST-A5 initiative on "Ageing and Technology" and TIDE R&D programme on "Telematics for Disabled and Elderly People". A wide range of products is being developed[2–4], using new technologies within robotics, telecommunications and information processing. In this chapter, telecare concepts and applications are discussed in terms of their potential benefits for cognitively impaired older people.

TELECARE CONCEPTS AND APPLICATIONS

"Telemedicine" is now well established worldwide and refers to the use of electronic information and communication technologies to link medical practitioners and patients[5]. This could include applications to support a wide range of medical practices, such as diagnostics, patient monitoring, therapy, rehabilitation and health education. "Telecare" is a more recent concept[6,7] and refers to the use of new technology to deliver and facilitate health and social care support services in the community.

New technology is likely to play a significant role in the community support of older people for several reasons[8]. Increasing numbers of older people have forced health and social services to look at more cost-effective approaches to care and support. Health and social care policy argues that most older people want to stay in their own homes and the improved services and enhanced levels of safety and security afforded by telecare systems may have the potential to help very disabled people to do so. Manufacturers and service providers have recognized the market potential for meeting the demand from older people and their carers for new products and related services. A number of telecare applications are available or being developed within several application areas.

Health and Social Care Information Systems

These are used to provide healthcare professionals and clients with health information. These can include simple operator-based systems, interactive websites and self-navigating information services using terminals in surgeries[6].

Client Support

Telecare can include telephone-based services to sophisticated medical systems utilizing state of the art telecommunications. These can be used to provide emergency response, counselling, training, information and client and carer support[9,10].

Client Records and Care Planning

Huston[11] argues that medical records are a weak link within telemedicine and telecare and outlines a model for a comprehensive medical records system. The EU-funded ITHACA project aims to provide a standard IT-based system for the assessment and planning of client care.

Assessment

Home-based technology can provide patient data that can be used for assessment and the specification of treatment and care. Doughty and Costa[12] outline a system to assess the ability of elderly people to live alone in the community, using sensors to provide electronic measures of activities that indicate functional performance after discharge from hospital.

Teleconsultation

This refers to the use of technology to facilitate communication between a healthcare professional and client. For example, Whitten *et al.*[13] report the use of a cable television interactive video system to deliver home health services from "telenursing cockpits".

Patient Monitoring

The most widespread technologies are community alarms or personal response systems[14], which allow a person to raise an alarm at a central control facility by pressing a button on his/her telephone or on a pendant worn around the neck. Recent work[15,16] has been aimed at developing a second generation of systems that use sensors in the home and artificial intelligence to automatically detect emergencies, even when a person is unable to raise an alarm him/herself.

Smart Housing

Smart housing helps frail or disabled people to live independently in their own homes by making the home environment more manageable. Remote control by dwellers, carers or care professionals and "intelligence" built into home systems means that some of the tasks of everyday living can be performed automatically. These include systems for controlling room temperature, home security, cookers, curtains, windows and so on.

TELECARE AND DEMENTIA

Despite considerable research and development activity in all the above areas, very little research has specifically focused on the needs of older people with cognitive impairments, and this remains a neglected area[17,18]. For example, only two of 32 projects, funded under the final phase of TIDE[3], made a reference to this client group, while none of the 127 R&D projects within the European Commission's Health Telematics programme[5] specifically mentioned people with cognitive impairments. This situation perhaps reflects assumptions made by engineers and designers about the abilities of cognitively impaired people to use and benefit from technologies. However, there may be considerable scope for new technologies for this client group within a number of key areas[19].

Supervision and Surveillance

A major concern in supporting demented older people at home is the potential safety risk involved, and the use of automatic alarms to highlight dangerous situations has received increasing attention from technologists and academics[18,20]. For example, wandering behaviour may pose a significant risk for an individual, as he/she may get lost or be unable to cope with the potential dangers of the outside world. However, restraint may be an undesirable or unethical option for wanderers. Simple sensors can be installed to determine whether a person has left a room or building and send a message to a carer or service provider. "Tagging" devices may be useful in locating people outside the immediate home environment.

Environmental Control

The home environment can be a dangerous place for cognitively impaired people. For example, they may leave cookers and heaters unattended, while gas and electricity are potentially lethal if misused. "Smart housing" technologies may be particularly useful for people with dementia, automatically shutting off devices or allowing remote control by carers or service providers. Smart housing could also use sensors linked to computers to control household appliances, devices, lighting and heating, depending on the movements and activities of the cognitively impaired person.

Quality of Life Care

The telecare applications discussed above generally focus on safety and security. However, there may be opportunities for more positive uses of technology to enhance the lives of people with dementia. For example, using technology to identify when a person is restless and bored and then initiating a familiar or enjoyable activity, such as playing familiar music or videos. Aromatherapy rooms could emit relaxing aromas to alleviate stress, while video telecommunications could help to reduce social isolation.

Carer Support

Carer support is a key aspect of care in the community. Using telecommunications to carry out more routine tasks, such as shopping or going to the bank or post office, may provide them with more free time, relieving the "burden" of care. Access to information advice and counselling is also important.

Reminder Devices

New technology could also provide "reminder devices" to support independent living. For instance, the TIDE-funded TASC project[3] aims to provide cognitively impaired people with suitable decision support software to help in carrying out household activities, social participation, communication and vocational tasks.

ETHICAL ISSUES

The discussion so far has highlighted the benefits of telecare. However, Sixsmith[16] argues that new technology can be a double-edged sword and that a number of potential problems need to be addressed:

- Will telecare increase the range of care options or will it just limit choice in a different way?
- Will the technology be intrusive, leading to an inevitable loss of privacy and dignity?
- Will the use of telecommunications mean the loss of human contact in the mental health care of older people?
- Will the introduction of new technology simply reflect marketing strategies, rather than the real needs of older people?
- Will financial savings made through the use of technology be reinvested in products and services or would it be another cost-cutting exercise?
- Will new technology just be used as another form of restraint to control the lives and activities of people with dementia?

CONCLUSION

This chapter has highlighted a number of potential areas for the development and application of new technology to support the independent living of cognitively impaired older people. However, it is clear that considerable research and development work is required if ideas are to become a reality. Moreover, there needs to be a shift in emphasis within research and development to reflect the specific needs of cognitively impaired people as well as those people with physical impairments (e.g. mobility, sensory, motor, control and manipulation). For physically impaired people, the underlying basis for technological development and design is to remove the environmental barriers that turn a person's impairment into a disability. In contrast, cognitively impaired people may have impaired abilities to understand their environment, formulate plans, carry out actions, communicate or remember what they have done or where they are. This has a number of implications for the development and implementation of telecare for this client group.

First, the inability to use a technology may be a serious limitation. Researchers and product designers will need to develop innovative ways of allowing cognitively impaired people to interact with the range of telecare systems, e.g. voice and visual interfaces, rather than traditional interfaces (keypads, etc.).

Second, the use of "smart" technologies may be a particularly useful approach for cognitively impaired people who are unable to

articulate their needs and desires. The idea of smart or ''proactive'' technologies involves the use of sensors and artificial intelligence to interpret a person's observable/physical behaviours and to anticipate his/her needs from these. For example, agitated behaviour patterns may indicate that a person is hungry or wishes to go to the toilet. The telecare system could then initiate some appropriate human or machine response, e.g. send a message to a carer or provide behavioural cues to the person him/herself. The information generated by these kinds of systems has the potential to provide a much more flexible, person-centred care regimen.

Finally, it is important that the implementation and application of new technologies are grounded in a thorough understanding of the individual within his/her social and care networks[17]. The needs and abilities of the person may vary considerably. People in the early stages of dementia may be able to cope reasonably well with only limited care, while others may require considerable help and support. Important individual factors to consider are level and stage of cognitive impairment, ability to carry out the activities of daily living, and problematic and emotional factors, such as anxiety and tendency to ''wander''. The informal and formal care networks will also determine the kinds of technological interventions that are needed. Again, this will vary from individual to individual, depending on factors such as availability of informal carer, physical proximity, carer network and capacity to provide care. The application of new technology needs to be tailored in order to complement the person's abilities and capacities and to provide help and support to care providers.

OVERVIEW

In the first edition of this book Fogel characterized the US system of health care for older adults with late-life mental disorders as a "non-system of care", plagued by irrational incentives and multiple access barriers[1]. This description highlighted a system that encouraged entrepreneurial activities among practitioners and health systems, was best at delivering specialized high-quality hospital-based care, and was constrained by perverse funding mechanisms that incentivized hospital-based and institutional care (nursing homes) but disincentivized outpatient and home-based care. While the individual elements of a comprehensive continuum of care could be found, services were described as fragmented, inadequate and poorly financed. As we move from one century into the next, considerable attention has been focused on the rapid changes occurring in health care and the changes that will need to occur in order to accommodate an aging population.

Has mental health care kept pace with these developments? Has much changed since Fogel's original assessment? Since the original report, the USA has struggled with the need to slow the growth of rising medical expenditures. The efforts to reduce global medical expenditures have centered on the application of managed care principles and practices and government cutbacks. The emphasis has been on cost reduction, not system's integration. In this chapter we will provide an update and overview of the current system of mental health care for older persons in the USA, with a specific emphasis on the organization and financing of services. The following components and trends will be addressed: (a) The structure and organization of mental health services for the elderly; (b) fee-for-service financing of mental health services for the elderly; (c) mental health managed care for older adults; and (d) emerging and future trends in integrated services and financing.

THE STRUCTURE AND ORGANIZATION OF MENTAL HEALTH SERVICES FOR THE ELDERLY

In an ideal system, the organization, financing and delivery of mental health services to the elderly would be a seamless continuum involving acute and continuing services across inpatient, outpatient and long-term care service settings, and networked with the general medical sector. Since mental disorders are a leading risk factor for institutionalization, improving the provision of mental health services in community settings is a major focus of public policy[2]. The following section summarizes current mental health service settings and highlights several demonstration projects designed to provide integrated care for the frail elderly.

Psychiatric Service Settings

Primary Care

Initial access to care for older adults is usually through the primary care sector, especially for older adults without a history of severe and persistent mental illness (SPMI). Many older persons prefer to receive treatment in primary care, and this service sector offers the advantages of proximity, affordability and coordination of medical and psychiatric co-morbidity[3]. Many older adults may present to primary care physicians (PCPs) with symptoms of mental distress, difficult to classify in current psychiatric classification systems[4]. The most prevalent disorders in the primary care sector are depression, anxiety, anxiety symptoms, dementia syndromes and misuse of prescription medications and alcohol use. Adequate detection, treatment and referral to the specialty mental health sector remain problematic, and have been attributed to such issues as: stigma; low priority of mental health issues in patients with serious medical disorders; inadequate referral resources; complexity of patient needs (psychiatric, medical and social); and lack of time and expertise in dealing with psychiatric problems[5]. Additionally, PCPs tend to approach psychiatric disorders using a medical model, which encourages over-reliance on medications for common disorders[6].

Despite the problems identified, PCPs will continue to be important mental health service providers. Thus, training in geriatric psychiatry and research that focuses on how to improve PCP effectiveness remains an important challenge for the coming decades[4,7]. PCPs will also be important mental health care providers for geriatric minority populations with late-life mental disorders in coming years[8].

Outpatient Psychiatric Service Settings

The proportion of psychiatrists reporting large geriatric case loads has steadily increased over the last two decades[9,10], a trend paralleled by other mental health providers, such as psychologists and social workers. More services are being delivered, in large part due to consumer demand, better treatments, an increased recognition of how untreated late-life mental illness contributes to excess disability, and more favorable Medicare reimbursement policies.

Through the American Psychiatric Association's Practice Research Network (PRN), we are just now able to describe a nationally representative profile of patient characteristics and treatments received from psychiatrists[11]. Similar practice-based research for other mental health disciplines has yet to be launched, and only recently have data been reported that describes the demographic and treatment characteristics of patients aged 65+ treated by psychiatrists[12]. Generally speaking, PRN psychiatrists provide a full array of diagnostic and treatment services for older patients. PRN provides descriptive baseline data. About 51% of patients aged 65+ in the PRN have a primary diagnosis of an affective disorder, followed by cognitive disorders (20%) and schizophrenia (19%). Older adults have more medical co-morbidities and lower initial global assessment of functioning scores. About 49% of older patients were seen in outpatient settings, followed by hospital settings (32%) and nursing home settings (16%). Over 50% of patients receive both pharmacotherapy and psychotherapy, and 40% of older patients receive pharmacotherapy alone. Only 2% receive psychotherapy alone. Of patients receiving medications, over 60% of older patients received antidepressants, 40% antipsychotics and 48% benzodiazepine medications.

Data are lacking on how well psychiatrists or other mental health clinicians employ best practices or adhere to existing treatment guidelines for older adults. Future research will be needed to answer these types of questions and establish the effectiveness of treatments for subpopulations of elderly patients, such as minorities, those living in different environments and those with significant medical–psychiatric co-morbidity.

Community Mental Health Centers

Older patients with severe and persistent mental illness (SPMI) pose significant challenges for the US system of care. These individuals have long-term care needs, have limited financial resources, and secular trends in managed care, home- and community-based alternatives to institutional care are being promoted as the major venue for mental health services[13]. About 2% of persons aged 55+ in the USA have SPMI, which is expected to double over the next 30 years[14]. The downsizing and closure of state hospitals over the last few decades has resulted in trans-institutionalization of SPMI patients into nursing homes and other less restrictive environments, such as boarding care homes, assisted living and other forms of community-based living arrangements. Currently, over 89% of all institutionalized older adults with SPMI reside in nursing homes[15]. It is unlikely that nursing homes will be a principal resource for care of older patients with SPMI, as further effects of nursing home reform (OBRA-87) and managed Medicaid are reinforced by patient preference[14].

Mental health services for the elderly SPMI population has been provided largely through community mental health centers (CMHCs). The CMHCs have not been particularly attuned to, or capable of, accommodating the unique and complex needs of the elderly, and they may not be capable of coordinating medical–psychiatric treatments[16]. Older persons with severe mental illness also receive services from home health agencies that provide limited mental health care and, to a lesser extent, from the general medical sector[14]. As with patients with less severe mental illness, older patients with SPMI require close collaboration among providers in the general and specialty mental health sectors. Promising models of integrated care include co-location of medical and mental health providers, multidisciplinary treatment teams and cross-training of medical–psychiatric providers. These programs must also include social support services to maintain function and improve quality of life, integrative case management services, home-based residential family support services, caregiver training and psychosocial rehabilitation[14]. Managed care may be the vehicle to promote such service integration because of the possibility of pooling resources from federal, state and local funding agencies. Appropriate risk adjustment mechanisms to account for the psychiatric medical and social service complexity of these patients will be required for programs to be successful.

Nursing Homes

In 1997 almost 1.5 million elderly resided in nursing homes. One-half of these people were aged 85+ and three-quarters were women[17]. Nursing homes have supplanted state hospitals as the major loci of institutionally-based long-term care for older adults with psychiatric disorders. Surveys of nursing home residents show uniformly high prevalence rates of dementia (46–78%)[18–20], and clinically significant depression (20–40%)[21]. Early in the trans-institutionalization movement, nursing homes became the repository of many SPMI patients. Current trends, however, find many older SPMI patients live in community settings[14].

OBRA-87 legislation, also known as the Nursing Home Reform Act of 1987, was enacted in response to inappropriate and inadequate care for mental illnesses in nursing homes. The legislation restricted the inappropriate use of restraints, physical and pharmacologic, and required pre-admission screening for all persons suspected of having a serious mental illness. Screening was designed to improve treatment and psychosocial assessment for nursing home residents with mental disorders. In 1998, the Institute of Medicine (IOM) convened a follow-up analysis examining the effectiveness of the original legislation. From a psychiatric services perspective, the results have been mixed[22]. Pharmacoepidemiologic evidence has shown a downward trend in the use of psychotropic medications, and interventional trials designed to reduce physical–chemical restraints in nursing homes demonstrated that educational efforts complementing consultation by skilled mental health professionals had the best results[23,24]. Physician prescribing practices have also changed. A new generation of psychotropic medications are now commonly being prescribed that have fewer side effects and are better tolerated by frail nursing home residents[25]. Multidisciplinary treatment guidelines have been developed to deal with difficult psychiatric and behavioral problems, such as depression and agitation, in dementia patients. Less certain outcomes of OBRA-87 include unnecessary tensions between the legitimate use of medications and federal/state survey procedures; collection of uniform information on nursing home residents that do not have sufficient flexibility to measure quality-of-life outcomes or quality indicators; logistic barriers for medically necessary psychiatric services; and the unintended effect of establishing incentives for the inappropriate provision of some mental health services, e.g. psychotherapy services for severely demented patients[22].

Important components in state-of-the-art mental health services in nursing homes include "intrinsic" and "extrinsic" mental health services[22]. Intrinsic services refer to the biopsychosocial elements of daily patient care activities and range from the nursing home environment to individual attitudes of professional staff, which are tied to respect, dignity and empathetic interpersonal exchanges. In addition, intrinsic services may include specialized settings and discrete units that provide behaviorally orientated services with highly trained staff. Dementia care units, "special care units" and psychiatric nursing home units are examples of specialized intrinsic services that are relevant to the treatment of older persons with mental disorders. Extrinsic services are linked to the ability of nursing home residents to gain access to specialized psychiatric services in a timely, efficient and sensitive manner. Extrinsic services generally refer to

specialized mental health services that are provided from outside the facility through a consulting or other contractual arrangements. A variety of consulting models of mental health services to nursing homes have been described and optimally include components of assessment and evaluation, with a strong emphasis on collaborating with the treating medical physician and on educating nursing staff[26]. However, surveys of nursing home directors indicate that there is considerable unmet need for psychiatric consultation services, especially addressing non-pharmacologic management and staff training. However, incentives are lacking for adequate service provision by psychiatrists in nursing homes and there are substantial challenges to identifying the most effective interventions and services[27]. Appropriate institutional and patient outcome measures need to be developed that can identify the most cost-effective intrinsic and extrinsic mental health services for nursing homes.

Acute Inpatient Hospitalization

Geriatric patients with late-life mental disorders requiring acute inpatient hospitalization are principally and appropriately cared for in secondary and tertiary care hospitals[1]. Inpatient units within general hospitals have access to subspecialist consultation and diagnostic technology required to provide accurate diagnosis and treatment recommendations. Over the last 15 years, there has been a substantial increase in the rate of admissions of geriatric patients to nine federal general hospitals. Specialized medical psychiatry units have increased the levels of sophisticated treatment for patients with severe mood disorders, mood disorders complicated by psychotic features, and those elder patients with mixed medical and psychiatric disorders[1]. Inpatient services offer multidisciplinary interventions, including psychiatric services, family evaluation and therapy, social service evaluations and, in ideal situations, coordinated aftercare services.

FINANCING MENTAL HEALTH CARE: THE UNDERPINNINGS OF THE CURRENT STRUCTURE OF THE US SYSTEM OF CARE

Ideally, health systems follow the rule that ‘‘form follows function’’. In the US system of care, a more cautious approach might be ‘‘form follows finance’’. In this respect, the character and dimensions of mental health services for older adults in the USA has flowed directly from the structure, incentives and limitations of the system of financing and reimbursement. In this section we will describe these recent developments in fee-for-service financing of mental health services for older adults, followed by a discussion of current trends in managed care. For geriatric patients with late-life mental disorders, Medicare is the principal payment source for acute psychiatric services in the USA. Aside from out-of-pocket expenses, state-managed Medicaid, a blended Federal and state insurance program for the poor, is the primary source of payment for institutional and long-term care services. Hence, we will concentrate on an overview of Medicare and Medicaid as the two principal sources of payment for mental healthcare services provided to older persons in the USA.

Traditional Fee-for-service Medicare

Medicare, the federally funded health insurance program, is the primary payer of acute general health and psychiatric care services for the elderly, people with chronic disabilities and people with chronic renal failure. In 1997, approximately 39 million individuals were covered by Medicare, of whom about 33.6 million were aged 65+. Total Medicare expenditures in 1997 were almost $207 billion and accounted for more than 11% of the US federal budget[28]. Medicare’s nearly universal coverage for the elderly is important because of the impact of adverse risk selection on insurance premium costs. Adverse risk selection refers to the attraction of high-cost consumers to insurance plans that offer coverage for high-cost conditions. In this respect, insurance plans that cover high-risk populations (e.g. the elderly, with multiple co-morbidities and chronic conditions) are likely to assume disproportionate risk compared to insurers covering services of younger populations with low use of expensive services such as acute hospitalizations and long-term care. In other words, the actuarial risk for high medical service utilization among the elderly is high. Thus, if Medicare were privatized and premiums reflected actual utilization, costs would be prohibitive for most older adults. This effect would be exaggerated for elders, as 11% of them live in poverty and another 6.4% are between poverty and 125% of the poverty level[28,29].

Traditional Medicare is similar to typical indemnity insurance products featuring retrospective fee-for-service (FFS) payment, deductibles and co-insurance, but it does not have limits on annual personal spending. It also does not fully cover medical equipment costs, and fails to cover prescription medicines and the costs of long-term care[28]. Cost sharing and uncovered benefits have created the private ‘‘supplemental insurance’’ market, the premiums for which constitute the largest source of personal spending for community-dwelling beneficiaries[28]. Supplemental policies may have inpatient and outpatient mental health benefits, designed to cover co-payments and deductibles. They do not alter basic coverage limits.

The proportion of Medicare expenditures devoted to mental health is relatively small, however. For example, in 1996 Medicare expended about $9.8 billion for mental health services, up from just under $5.1 billion in 1994[30,31]. Most Medicare expenditures for mental health services are for Part A services, and less than one-half of 1% are for older adults in non-institutional settings[32,33].

Medicare’s Benefit Design for Mental Health Services: Fee-for-service and Managed Care Arrangements

Traditional FFS Medicare has two components; part A, which covers inpatient psychiatric hospital care (up to 190 days life-time maximum in free-standing psychiatric hospitals and unlimited days in general hospital psychiatric units) and outpatient care in some hospital-based clinics and other hospital technical fees[34]; part B covers medically necessary physician, partial hospitalization and related ancillary services. Psychotherapy services provided by psychiatrists, non-psychiatric physicians, psychologists and other mental health providers, as well as outpatient electroconvulsive therapy are subject to a 50% co-payment, while medical management services are subject to a 20% co-payment[34].

Since the enactment of the Medicare legislation in 1965, reimbursement policies have been a financial barrier to accessing needed mental health services for the elderly and disabled, especially for outpatient services. Until reforms were enacted in the late 1980s, Medicare’s inpatient coverage was similar to private insurance, while outpatient service coverage was de minimus[35]. For example, Medicare reimburses inpatient services carefully, less a 1 day deductible for the first 60 days; it requires a 25% co-payment for days 61–90 and a 50% co-payment for days 90–150[34]. In contrast, in 1966–88 Medicare covered outpatient mental health services up to a maximum of $500, subject to a 50% co-payment, e.g. Medicare only paid $250. In 1984, limitations on medically-based psychiatric services for Alzheimer’s disease were not subject to the $500 and 50% cap. The Omnibus Budget

Reconciliation Acts of 1987 and 1989 (OBRA-87 and OBRA-89, respectively) changed reimbursement for outpatient psychotherapy services. OBRA-87 raised the $500 cap for psychotherapy reimbursement to $2200, but retained the 50% co-payment, effectively paying only $1100. OBRA-87 exempted medical management of psychotropic medications from the limit, in addition to reducing the co-payment to 20%. Partial hospitalization services were authorized. OBRA-89 removed the cap on outpatient mental health services, although the 50% co-payment was retained[35].

Changes in benefit design contributed to increasing expenditures for mental health services by 136% between 1987–1992[36]. Correspondingly, service utilization increased, thus correcting the historic underutilization of mental health services by the elderly, e.g. mental health service users rose 76%, and the number of services per beneficiary over age 65 years rose 15%[36]. Difficult to estimate, however, are expenditures for mental health services delivered by physicians in general medical settings, which reflect actual treatment services for psychiatric conditions not coded by providers or treatment services for psychiatric conditions misdiagnosed as general medical disorders.

Although increases in expenditures for mental health services provided to older persons over the last decade suggest that progress has been made in better meeting the need, it is important to note that most of the services remain biased towards costly inpatient care. In 1994 about 12.7% of Medicare claimants had a MH/SA disorder based on primary diagnosis and/or procedure codes[37]. Cano *et al.*[38] estimated that in 1995 Medicare beneficiaries aged 65+ with a primary psychiatric diagnosis accounted for 325 000 hospital and skilled nursing facility stays and accounted for approximately $1.8 billion or 53% of all acute psychiatric payments made by Medicare. The majority of admissions were to psychiatric units in general hospitals (42%), followed by general hospital admissions (29%), psychiatric hospitals (15%), and skilled nursing facilities (14%). Overall, the burden of mental disorders in the elderly is substantial; Smyer and Shea[39] estimated that the total direct costs for mental illness for individuals aged 65+ were $17.3 billion.

Medicaid

Medicaid is the primary public insurer for acute care for medically indigent populations and for long-term care in the USA. Medicaid is a joint federal and state program, with an individual state contributing up to 50% of costs. Variability in benefit design among states makes it difficult to generalize about the effects of Medicaid on care nationally[14]. For example, states differ on eligibility criteria (this applies to people eligible for both Medicare and Medicaid), on the scope of coverage for inpatient and outpatient mental health services, pharmacy benefits, co-payment arrangements for enrollees, pre-authorization rules for inpatient and outpatient services, and managed care arrangements. Common to Medicaid programs, however, is a 20–30% reduction in reimbursement schedules compared to regional market rates[14].

Figure 127.1 summarizes national Medicaid expenditures in 1995. Excluding administrative expenses and disproportionate share allocations to hospitals serving large numbers of poor people, Medicaid spent about $132 billion in 1995 on about 34.8 million recipients, of whom only 11% were aged 65+. However, this latter group accounted for about 30% of all expenditures. About 19% of Medicaid expenditures were spent on nursing facilities, 6% on home health services, and only 2% on mental health services[40]. It is difficult to determine what proportion of the $7.1 billion in Medicaid expenditures for mental health services in 1994 was for older adults[31]. Medicaid spent approximately

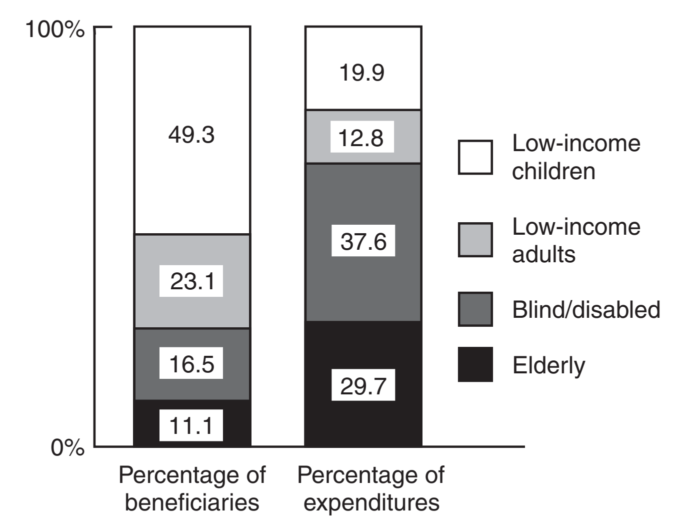

Figure 127.1 Distribution of Medicaid beneficiaries and expenditures in 1995: $132.3 billion for 34.8 million recipients. Adapted from MedPac

$10 129 per elderly beneficiary, and 75% of this amount was allocated to long-term care services[40].

Mental Health Managed Care for Older Adults

Over the last decade, managed care has had stunning impact on private commercial and public financing and delivery of mental services in the USA. While universal definitions of managed care have not been agreed upon, for the purposes of this chapter, managed care is defined as systems of care that integrate the financing and delivery of appropriate healthcare services to health plan enrollees by means of provider network arrangements. Managed care organizations (MCOs) furnish comprehensive healthcare services; set standards for the selection of providers; use formal and ongoing quality improvement and utilization review programs; and place emphasis on preventive services in order to avoid more costly medical care services. MCOs use incentives to use health plan providers and services in order to limit out-of-network providers[41]. Recall this definition of managed care later in the chapter, when we discuss demonstration projects designed to integrate geriatric healthcare services for the frail elderly.

To a large extent, managed care has succeeded in reducing healthcare expenditures in both the general health sector and specialty mental health sector, especially for private commercial health plans. For example, under the Federal Prospective Payment System (PPS) to hospitals, inflation in global operating costs per hospital case declined from a yearly average of 9.5% during 1985–1990, to a yearly average of −0.5% during 1993–1997[42]. The rate of growth of global physician expenditures has also declined. Using the Medicare Economic Index (MEI), which measures various inputs used to produce physicians' services, such as earnings, staff salaries, supplies, etc., MEI increases in 1985–1992 averaged 3.1%/year, but have declined to 2.1%/year since 1992[43]. In the non-Medicare specialty mental health sector, cost reductions have also occurred. The Hay Group Management Corporation and the National Association of Psychiatric Hospital Systems (NAPHS) recently reported that the value of behavioral healthcare expenditures for commercial insurance plans (non-governmental insurance) decreased in 1988–1997 by 54.1%, compared to 7.4% for general healthcare costs[44]. As a proportion of total healthcare benefit costs, behavioral health benefits

decreased from 6.1% in 1988 to 3.1% in 1997. The disproportionate reduction in behavioral health benefit expenditures can be attributed to both impositions on utilization patterns (24.6% decline in outpatient utilization) and benefit design (57% of plans imposed day limits on inpatient care, and 48% placed outpatient visit limits by 1997)[44].

Medicare Managed Care and the Balanced Budget Act of 1997

Encouraged by the private sector's success in managed care, coupled with rising healthcare costs, federal initiatives have stimulated the growth of Medicare managed care, especially since the enactment of Public Law 105-33, the Balanced Budget Act of 1997 (BBA-97). According to the Department of Health and Human Services' Health Care Financing Administration (HCFA), about 6.1 million Medicare beneficiaries were enrolled in Medicare risk-managed care plans by December, 1998[45]. The enrollment growth has slowed in 1998–1999 and Health Maintenance Organizations (HMOs) holding nearly 100 risk contracts have indicated that they will withdraw from Medicare managed care in 1999 (about 409 000 enrollees) because of payment rates and regulatory burdens[45]. Medicare predicts that about 44.5 million Medicare beneficiaries will be in managed care programs by 2008[46].

Several managed care options existed for Medicare patients prior to the BBA-97. These included Medicare risk contracting (MRC) plans, point of service options (POS), social HMOs or demonstration projects called programs of all-inclusive care for the elderly (PACE). Social HMOs or PACE programs are demonstration projects that combine Medicare and Medicaid funding into one funding base, providing a continuum of healthcare services, including inpatient, outpatient and long-term care[5]. The BBA-97 created the Medicare + Choice program, a new Part C of Medicare. Medicare + Choice expanded these options to include medical savings accounts, POS options that allow patients to select from a broader panel of practitioners outside of the HMO network, religious fraternal benefits plans, and other coordinated care plans meeting a set of established standards[46].

MRC plans are the most frequent type of Medicare managed care arrangement. A MRC plan receives a set payment per month per patient, based on a county level adjusted average per capita cost (AAPCC), as determined by HCFA. The BBA-97 made significant changes in the payment methodology to MRC plans that have had historically high AAPCC payment rates. Beginning in 2000, the risk adjustment methodology used to pay many HMOs also changed, further reducing HMO payment rates[47]. To remain solvent, MRC plans must ensure that their costs do not exceed the AAPCC payments. Concerns over the payment methodology have forced some plans to leave the market, while others have reduced benefits and increased co-payments and premiums.

By law, MRCs must offer basic Medicare benefits, including mental health benefits. In order to entice Medicare beneficiaries into joining Medicare HMOs, many plans offer enhanced supplemental benefits, such as prescription drug benefits, dental coverage, optical or hearing services[47]. Neither HCFA nor the managed care industry has established policies or procedures for how mental health services should be delivered to the elderly. Largely undefined, or using criteria from commercial managed care plans, are medical necessity criteria, co-payment policies, credentialing standards for providers, hospital network standards, geographic access rules, referral mechanisms and quality improvement mechanisms[5]. Case management guidelines, coordinated care for patients with medical–psychiatric co-morbidity, dementia care and long-term care policies (beyond the 90 day rule for skilled nursing home care) have not yet been clarified. These plans may also fail to risk-adjust for chronicity and medical–psychiatric co-morbidity of late-life mental disorders, such as Alzheimer's disease or recurrent major depression[35].

Managed Medicaid

Over the last several years, many states have created Medicaid managed care arrangements. As of 1996, about 38.6% of all Medicaid beneficiaries were under Medicaid managed care arrangement, and increased 12% during 1995–1996[40]. The move to Medicaid managed care has been encouraged by program waivers from the Federal Government under Section 1915(b) and Section 1115 of the Social Security Act[40]. Section 1915(b) allowed states to mandate enrollment into managed care programs. Section 1115(a) allowed the US Secretary of Health and Human Services to approve time-limited demonstration projects that test and evaluate innovative approaches to delivery and financing of health care. Section 1115(a) also allowed some states to expand Medicaid eligibility for acute care services; however, it has been used to enroll Medicaid beneficiaries into prepaid managed care programs[40]. The impact of these new financial arrangements on access to mental health and long-term care services by older persons is yet to be determined. The degree to which state-run Medicaid programs will reallocate resources away from long-term care programs used by elders towards children and low-income families is also unclear.

Mental Health Managed Care Arrangements: The "Carved-out" vs. "Carved-in" Debate

Most Medicare MRC plans "carve out" the mental health benefit package, similar to what they do for commercial patient populations. Mental health "carve-outs" refer to the practice of setting aside funds for mental health benefits and then contracting with a vendor, who is responsible for managing all mental health services. Benefits of carve-out mechanisms include protection of the HMO from expenditures above the contracted percentage of premium paid to the carve-out vendor, reduction of HMO staffing and space needs, patient confidentiality and mental health professional input for difficult cases. Proponents of carve-outs purport that these financial arrangements for mental health services are superior because vendors are able to manage costs and services through superior technical knowledge, skills and service delivery networks[58]. "Carve-out" approaches to Medicare managed care may not be the best approach for older adults because of medical–psychiatric co-morbidities. These arrangements may not provide coordinated psychiatric and primary care services[48]; may restrict physician involvement through profiling and paneling[49]; may increase access barriers to care[50]; and may limit the quantity of needed services[51]. Carve-out arrangements may pose problems with demonstrating cost offset for mental health services, especially for those patients with significant medical–psychiatric co-morbidity[14]. A study of dominant carve-outs providing service to MRC payers demonstrated little or no requirement for specialty-trained providers or evidence of experience in caring for the elderly[52].

Some argue that mental health benefits for older adults should be "carved-in", e.g. where mental health services are included as part of the general health benefit. Advocates argue that this benefit design better integrates mental and physical care, decreases access barriers due to stigma, and produces cost offsets in general healthcare expenditures because of the high medical–psychiatric co-morbidity among older adults[14]. Other benefits include better collaboration among psychiatric and physical health providers, as

Table 127.1 Selected features of managed care programs for the frail elderly: PACE, social health maintenance organizations (S/HMOs), and EverCare programs

Characteristic	PACE	S/HMO	EverCare
Setting	Community setting	Community setting	Nursing home
Start-up	1971, On Lok Program 1990, PACE	1985, first generation of S/HMO 1997, second generation of S/HMO	1994
Number of active programs in 1999	25	First generation, 3 Second generation, 1	Six demonstration projects
Focus	Integrate delivery and financing of acute and long-term care for frail elderly	First generation: test models of integrating acute and long-term care, and social services in a capitated HMO setting Second generation: required improvements in service, and benefit design including: geriatric assessments, multidisciplinary teams, expanded case management services for individuals at risk for disability	Enrolls permanent nursing home residents into managed care programs with a focus on providing Medicare covered outpatient services in order to reduce hospital and emergency room use
Eligibility requirements	Eligible enrollees must meet state nursing home eligibility requirements	Initially limited to frail beneficiaries aged 65+	Nursing home residents
Benefit structure	Acute and long-term care benefits covered through Medicare, Medicaid and private capitation payments. Prescription drugs are covered	All Medicare benefits, expanded benefits (similar to typical Medicare Risk Contracts), and long-term care benefits. Prescription drugs are covered	Similar to Medicare Risk Contract but no prescription drug benefit
Enhanced mental health services	Not addressed	Not addressed	Not addressed

Adapted from MedPac[56].

well as improved psychiatric services for those older patients who receive most of their mental health service from primary care providers. Carved-in benefit designs are not without hazards. Functional integration of mental and general health services are far from guaranteed, and mental health services are likely to receive low priority in these types of managed care arrangements. Comprehensive services for mental health, e.g. parity, may not occur, and payment methodology that adequately risk-adjusts for the more seriously ill patients are not well developed, thus placing a health plan at risk for substantial financial loss[14,53].

EMERGING AND FUTURE TRENDS IN INTEGRATED SERVICES AND FINANCING

While recent legislative changes in Medicare and Medicaid have incentivized some efforts toward the goal of a seamless continuum of care for the most frail and vulnerable geriatric patient populations, much work remains. Promising demonstration projects have emerged, such as out-of-pocket-financed community-based dementia respite care programs[54]. While Medicare's psychiatric and mental health benefit has been liberalized over the last 13 years, parity between mental health and general health care benefit coverage has not occurred. Nevertheless, the BBA-97 expanded three demonstration projects designed to care for those frail Medicare beneficiaries who need more long-term chronic and acute care. Programs include the program of all-inclusive care for the elderly (PACE)[55], social health maintenance organizations (S/HMOs) and the Evercare Demonstration Projects care[56]. These programs were not specifically designed for older adults with late-life mental disorders; however, because the frail elderly are at increased risk for psychiatric illness, mental health services will be part of the package of services.

Table 127.1 summarizes the select features with PACE, S/HMOs and the Evercare programs. PACE is a community-based program that is designed to delay or prevent the use of hospital or nursing home care by providing a comprehensive range of preventive, acute and long-term care services in community settings. The first generation of S/HMOs was designed to test the integration of financing and service delivery of a full range of acute and long-term care services through capitated HMOs. The second-generation S/HMOs have expanded programming, including such services as geriatric assessment, case management services and a multidisciplinary team approach to care. EverCare is a program that enrolls permanent nursing home residents into managed care programs and provides "in-place" primary care services to nursing home residents[56]. Primary care services include both acute and preventive services, provided within the nursing home setting.

All three programs use managed care financing, case management principles, and provide a wider array of medical and social services. Enrollees in the S/HMOs have similar demographic characteristics to those beneficiaries enrolled in Medicare, but PACE and Evercare enrollees are significantly older, and a higher proportion of them are Medicaid-eligible. Unfortunately, none of these demonstration projects have specific requirements for the provision of mental health services, although the profile of beneficiaries expected to enroll in these programs would have considerable psychiatric co-morbidity. Program evaluations for the PACE Program and S/HMOs have demonstrated mixed outcomes. For both PACE and S/HMO, enrollee satisfaction was generally high[56], although enrollees in the S/HMO with physical impairments were usually less satisfied[57]. Psychiatric outcomes have not been measured to date.

SUMMARY

The last half of the twentieth century included an explosion in the size of both the older-adult population and the US healthcare system. Since the introduction of Medicare and Medicaid in the

1960s, older adults have had universal access to acute health care and their demand for services has driven the development of a highly capitalized, technologically advanced but severely fragmented system. This interaction has contributed to the extension of life expectancy, a probable improvement in life quality for many, and staggering growth of expenditure. The last two decades have been consumed by efforts to contain and reduce costs, despite continued technology growth that has had marginal effect on efficiency. Throughout this period, mental health has been, at best, a poor stepchild. While enjoying advances in science and recognition of its importance, the care of older people with late-life mental disorders has evolved services that reflect modest reimbursement schemes while attempting to meet a minimal subset of population needs. The provision of mental health services for the elderly is inextricably linked to primary care and, for the frail elderly, must attend to the problems of medical–psychiatric co-morbidity. Recent reforms in the organization and financing of health care are beginning to address co-morbidity issues through integrated acute and long-term care delivery systems, such as PACE, S/HMOs and the Evercare programs. State Medicaid managed care initiatives are also creating opportunities to reallocate support to the development of home- and community-based alternative models of care, with the goal of supporting least restrictive and less costly long-term care services. Demonstration projects must examine behavioral outcomes and analyze their effects on general health, mental health, functional capacity and quality of life. Yet to be determined is the impact of these types of programs on increasing access to medically necessary mental health services.

At the dawn of the new millennium and in the face of extraordinary projected population growth of those aged 65+, opportunity must be seized from innovation. The shift of some insurance risk to providers from payers and the government may be perilous, but it is the first opportunity to align incentives to benefit the populations we serve.

Community-based Psychiatric Ambulatory Care: the Private Practice Model in the USA

Elliott M. Stein and Gary S. Moak
Private Practice in Miami Beach, FL, USA

In the USA, ambulatory or outpatient psychiatric care of individuals in later life is provided in a variety of public and private office settings. These include publicly-financed community mental health centers, hospital-sponsored outpatient clinics or services, the offices of psychiatrists (and other mental health professionals) in private practice, health maintenance organizations (HMOs, both privately and government-funded), and others. This chapter will focus on practical aspects of providing psychiatric treatment to older Americans in office-based psychiatric private practices. We will not discuss the details of treatment in these settings, but rather the "mechanics" of the process. An important focus of community-based psychiatric ambulatory care is the need to create relationships with other community services and providers of care and assistance. This provides both a framework and a means by which many of the services are provided. Some of the barriers and obstacles to care will also be reviewed.

In providing community-based ambulatory care, the psychiatrists must have a comprehensive and patient-centered focus, following the patient to provide whatever psychiatric treatments are needed in whatever setting. While there are some geriatric psychiatrists who limit their activities to specific treatment locations, such as in offices or in-hospital programs, this type of care may require the patient to be seen and treated sequentially in many places and circumstances.

INFLUENCES ON PRIVATE PRACTICE

For the purposes of this chapter, we will define private practitioners as independently employed or self-employed psychiatrists who work alone or in small groups. These practitioners provide treatment to patients who individually seek their help, and who pay for services received, primarily with Medicare health insurance benefits. Notwithstanding the large-scale reorganization occurring in the American healthcare system, private practice remains the widespread model of medical practice in the USA. In many ways it has served as a starting point for the pattern of care provided in the other settings mentioned above. Many of the techniques discussed below are applicable to other models of treatment. Older patients seek care from private practitioners or other mental health providers with varying degrees of utilization and satisfaction[1,2].

The private practice of medicine in the USA has evolved as a cottage industry within an historically unsystematized, free-enterprise, fee-for-service climate. Changing lifestyle preferences and demographics among young physicians are having some impact on this pattern. From its inception in 1965, the Medicare system has had a built-in prejudice against the provision of outpatient psychiatric services. There remains a discriminatory 50% patient co-payment requirement for all psychiatric treatment services delivered outside of an acute care hospital setting (unlike all other covered medical services, for which the patient co-payment is 20%). This has constrained provision of these services to the elderly. Over the past 5–10 years, however, much greater influence has been felt from a multitude of outside forces, at times impeding geriatric psychiatry practice[3,4], but in some cases expanding it. These forces (to list a few) include: efforts by the federal government to rein in Medicare spending[5,6]; the penetration of health maintenance organizations (HMOs) into Medicare; the advent of federal nursing home reform regulations; the growing presence of healthcare agency accrediting bodies, such as the Joint Commission for the Accreditation of Healthcare Organizations (JCAHO) and the National Council of Quality Assurance (NCQA); the creation by the American Board of Psychiatry and Neurology of subspecialty board examinations in geriatric psychiatry; social attitudes (e.g. public attitudes about medical care and doctors, as well as about mental illness and psychiatric care); the influences of physician attitudes[7] and medical malpractice litigation[8]; the availability of newer psychopharmacologic agents (including their increased acceptance by the public and their increased utilization by primary care physicians); patient finances; and folklore and "common sense" of both the professional and the general population. Geography also is a factor, as there is significant regional variation among practitioners and communities in different areas of the country. Adaptation of geriatric assessment and treatment principles has been slow, for the most part, in private medical practice. Nevertheless, successful practitioners need a working knowledge of these forces in order to function. As a relatively new field in the USA, there are few established examples of psychogeriatric care that have proven generally applicable. In fact, the fee-for-service system in the USA has thus far been a relative failure in geriatrics, since it has not incorporated many of the accepted principles of geriatric care[9].

The incursion of managed care HMOs into the Medicare system held out promise to change this state of affairs. HMOs, in theory, employ methodologies such as integrated delivery systems, screening, prevention and case management that are ideally suited to geriatrics[10]. Their track record has been disappointing, however, and their approach to managing mental health care has been largely ineffective for the elderly. Managed care

companies often "carve out" the management of mental health services by subcontracting it to managed behavioral healthcare companies with specialized expertise in mental health benefits management[11]. Such companies rarely have any expertise in geriatrics, and do not appreciate its differences from general adult psychiatry[12]. These companies have often ageist attitudes built into their coverage utilization guidelines, and inappropriately limit treatment or completely deny it, especially involving members with Alzheimer's disease, which they do not view as a covered psychiatric disorder. To the extent that managed care has penetrated Medicare, this practice has made the practice of geriatric psychiatry unnecessarily burdensome for many American psychiatrists.

PRIVATE PRACTICE AS A BUSINESS

Another important factor in discussing this type of psychiatric practice is the awareness that it is a business, and that the patients are customers. As such, it behooves the psychiatrist to organize the practice and to provide services in ways that answer the needs of these customers. The psychiatrist may help the patient to define these needs, provide information about them, alter them, or aid them in various ways. The psychiatrist may need to refuse patients' requests when professional judgment dictates this. American consumers, especially the adult children of geriatric patients, are becoming increasingly distrustful of the healthcare system and doctors. If the psychiatrist does not do a good job or does not adequately address at least some of the patient's needs (and/or their adult child's needs), the psychiatrist may lose that patient's business. Thus, it is clear that the interaction between them is an exchange of service for payment. By providing a comprehensive service, as mentioned above, the psychiatrist may provide more services in more locations, which is often very satisfying and helpful to patients. At the same time, the business opportunities for income are maximized. In a community-based private practice, people are often referred to the individual doctor, rather than to a hospital, a university or a public clinic where they may be assigned a doctor. Patients may be referred because of the doctor's quality of service, reputation or relationships with the referring party. These qualities therefore become significant aspects of the psychiatrist's success in business as well as clinical practice.

Important factors in satisfying the patient/customer include:

1. *Cost*: reasonable fees and/or helpfulness and knowledgeability in filling out insurance claims.
2. *Accessibility*: convenient and comfortable office location and surroundings.
3. *Availability*: the availability of the psychiatrist to go to the patient if needed (e.g. to consult at a medical hospital if the patient is admitted by another physician for a physical ailment, or to see the patient at home, in a nursing home, or an assisted living facility) is very important. The convenience of the geriatric psychiatrist going to where the patient lives, rather than the patient coming to the doctor's office, is very attractive to family caregivers responsible for transportation. The viability of this form of practice, in private practice, depends upon arrangements with facilities that ensure an adequate volume of patient visits for each trip to the facility.
4. *Scheduling*: flexibility to see patients at convenient times without excessively long delays in scheduling appointments. This is crucial, since many frail patients are brought by their adult children who work.
5. *Communications:* the ability to contact the psychiatrist quickly and easily at need (e.g. by telephone by the patient and, when appropriate, by the patient's family). This includes the willingness of the psychiatrist to return such phone calls quickly, and the friendliness and accuracy of the psychiatrist's secretary or answering service. It also includes the ability and willingness of the psychiatrist to speak to the patient (and family) about his/her symptoms, illnesses and treatments in a clear and patient manner.
6. *Concern*: the feeling that the therapist has a genuine interest and concern for the patient. This feeling of concern extends to the patient's interactions with the office staff. This is an especially vital factor for the older population[13].
7. *Confidence*: patients need to feel that the psychiatrist knows what the patient's problem is and has an idea about what can be done. The doctor does not need to define answers, but must indicate a grasp of the situation and some ideas for an approach to it. This helps to provide a structure to what is often a strange and frightening experience. Empathy with the patient's distress is very helpful in this, as is reassurance to the patient that his/hers is not the worst case the doctor has ever seen (a common fantasy).

There are only limited data available on income and workload for geriatric psychiatrists as a group. For all psychiatrists, 1998 median annual gross income was $171 490 (a 3.5% increase from 1997) and annual net income was $118 630 (a 4.33% increase from 1997). This was the second lowest income of the 20 largest specialties (above general practitioners) surveyed by Medical Economics that year. The rate of inflation in the year 1997–1998 was 1.6%. Comparable 1998 income data for all US physicians show an annual gross income of $256 290 (down 0.7% from 1997) and a net income of $163 940 (up 2.2%); for non-surgical specialties the gross income was $227 300 (up 1.7%) and the net income was $147 140 (up 2.4%)[14]. When these data are compared to the median annual net income for psychiatrists in the USA in 1989, which was $103 570 (the fourth lowest of 15 office-based specialties surveyed that year; the only doctors who made less were general practitioners, family physicians and pediatricians)[15], we find that the income of psychiatrists had risen 14.5% in that period. The median net income for all fields of medicine rose just under 25% during the same period, while the cumulative inflation rate added up to 35%.

Although most American psychiatrists see few or no geriatric patients, this trend is changing somewhat. There were over 5400 out of the over 36 000 members of the American Psychiatric Association who expressed an interest in geriatrics during their 1997–1998 Professional Activities (Biographical) Survey[16]. The membership of the American Association for Geriatric Psychiatry has grown to over 1800[17] and interest among general psychiatrists is increasing. In 1991, the American Board of Psychiatry and Neurology first administered a Board Certifying subspecialty examination in geriatric psychiatry. As of September 2000, there were 2508 individuals who have passed this examination[18].

In 1996, 18% of American general psychiatrists had geriatric caseloads exceeding 20% of their practices[19]. Overall, in this 1996 survey of 970 responders, an average of $14.0 \pm 17.7\%$ of their psychiatric patients were aged 65+[19], compared to 8.4% found in a 1987 study[20]. When psychiatrists who provide a higher proportion of geriatric services (more than 20% of their case load—HGPs) were compared to those who were low-volume providers with the elderly (less than 20% of their workload—LPGs), it was found that the HPGs spent proportionately less time in their offices (although still spending most of their time there), more time in hospitals and significantly more time in nursing homes, than LPGs[19]. In view of relatively low numbers of psychiatrists with a specific interest treating the elderly, when the medical and general communities know that a particular psychiatrist is a geriatric specialist, there is usually no shortage of patients needing these services.

OFFICE PLANNING AND DESIGN[21,22]

Establishing a practice to treat older patients requires some attention be paid to the setting in which such treatment will occur and to factors that might act as barriers to treatment. Offices that can only be reached by climbing stairs, or those with varying levels into which one must step up or down, are difficult and potentially hazardous. Long corridors that must be traversed are similarly problematic. Chairs should be available that are sturdy and have armrests and firm seats, high enough for ease in sitting or rising. Adequate lighting, readable signs and patient information literature should be planned with poor vision in mind. Area carpets, spring-hinged doors and other possible hazards should also be considered.

Mobility and transportation problems are another potential obstacle to treatment. Selection of an office location in a rural community, or in an area with poor public transportation or poor handicapped access, may be factors. Treatment may be interrupted during the winter months if the cold interferes with the patient's ability to get to the office. Some communities have senior transportation services, which will take people with limited mobility to physicians if reservations are made 24–48 hours in advance. Some hospitals may transport patients to and from the hospital or to physicians' offices located in adjoined buildings. Offices may also be located in senior retirement buildings or communities.

THE BEGINNING OF THE RELATIONSHIP

Older patients seek out, are referred to or are brought to the psychiatrist's office for care. An initial "gatekeeper" function may occur by means of inquiries (usually by telephone) into the reasons for the request to be seen, the age of the prospective patient, the referring source, the status of insurance coverage or other financial information. Such inquiries may lead a particular practitioner who prefers to specialize in geriatrics to decline to accept an adolescent as a patient, or to suggest that a patient being seen by another psychiatrist first discusses the idea of transferring with the current therapist, or to refer the patient to a geriatric psychiatrist in a geographically more convenient location.

A prospective patient, once given an appointment, should be told about additional information the psychiatrist would like to have available at the time of the first visit (e.g. the names of the patient's other treating physicians, current medications being taken, information about past psychiatrists, psychiatric medications, hospitalizations, etc.). If the referring source is a physician, family member or a member of the staff of a senior-living facility, information from them as to the nature of the problem referral may be requested.

THE RANGE OF SERVICES

Among the most important services a psychogeriatric specialist can provide are diagnostic services. Too often, inadequate or erroneous evaluation leads to inadequate or erroneous treatment. A knowledge of physiology, psychology and the illnesses of late life, a comprehensive approach to history taking, assessment and testing and the ability to formulate an appropriate treatment plan form the basis of a unique contribution by geriatric specialists[23,24]. In fact, the ability to provide such a comprehensive evaluation and treatment perspective may be a primary reason why patients and referral sources seek the assistance of a geriatric psychiatrist.

An important aspect of the coordinated treatment plan is the collection of past information. With the patient's permission, contact is established with the patient's family, other physicians and therapists. Past records, diagnoses, psychological testing reports, doctors' treatments, psychotherapy records, laboratory and radiological reports are collected. While not revealing confidential information, these contacts also benefit the patient by making the patient's other physician and support system aware of your activities with the patient. This increases the likelihood that you will be notified of future problems that may occur and that other medical treatments will be coordinated with you by other physicians. In the absence of such relationships, physicians may call a different psychiatrist to provide treatment, due to lack of awareness of your involvement.

As has been reviewed elsewhere[22,25,26], including sections of this volume, older individuals can be suitable candidates for many of the therapeutic modalities provided to younger patients, including individual, group and family psychotherapies, which utilize insight-orientated, cognitive, behavioral and other techniques. Some approaches, such as reminiscence or life-review therapy[27], have more specific applicability to the aging person. Modification of family therapy may be necessary, e.g. to address the role of adult children in assisting in the care of a demented or otherwise impaired parent.

Unfortunately, the federal government has been increasingly scrutinizing and denying payment for psychotherapy services for Medicare beneficiaries, including many elderly patients. Under the Clinton Administration's program "Operation Restore Trust", an effort to reduce fraud and waste in the Medicare and Medicaid programs, many psychotherapy services came to be viewed as unnecessary or fraudulent, particularly those provided to demented patients or in nursing homes[28,29].

Psychopharmacologic treatment of the elderly often requires alteration in the selection, dosing and scheduling of medication because of changes in absorption, distribution, metabolism, receptor sensitivity and excretion[30,31]. Once again, the geriatric psychiatrist may be sought out in recognition of this expertise by the patient and others involved in the patient's care. Pharmacoeconomic trends in the USA create additional conflicts for geriatric psychiatrists in private practice. First, many patients who have Medicare have no prescription drug benefits (although this was an important political issue in the US presidential election of 2000). Pharmaceutical costs are escalating rapidly in the US compared to many other countries. Patients may have coverage for the physician visit but not the drugs the physician prescribes[32]. Those beneficiaries who have opted for managed care plans may have some drug benefits. However, treatment options are often limited by restrictive formularies designed with cost containment in mind, but often without any consideration of the greater sensitivity of elderly plan members to medication side effects. Nursing homes have also adopted formularies to contain their costs, even in the absence of significant managed care penetration. Consultant pharmacists are employed by the homes to monitor physician prescribing, with respect not only to federal regulations but also to formulary requirements. Psychiatrists in private practice are thus often under pressure to prescribe less costly drugs or to run the risk of receiving fewer referrals from primary care physicians or nursing homes.

Sometimes assistance provided may be primarily educational, such as telling the patient or his/her family about the nature of the aging process or the symptoms, prognosis and treatment of an illness. Treatment may be primarily informational, directing patients and carers to appropriate senior housing, services for the blind or hearing-impaired, continuing education programs or volunteer work. At times treatment may be directive, e.g. telling a patient to get a physical examination, buy a hearing aid or give up driving, or telling a family member to seek the assistance of respite services to provide some relief in caring for a cognitively impaired person, or to advise that the parent or sibling should no longer

live alone. The community-based psychiatrist must develop expert knowledge of the available community resources, as well as relationships with the providers of them.

The initial psychiatric diagnostic evaluation of the patient also is the time of the patient's actual evaluation of the doctor. The practitioner must address the overt and covert concerns, the anxieties and fantasies about the nature of geriatric psychiatry, the reasons why the patient is there and the treatments that will be instituted. Although these anxieties are not unique to this model, the need to address them is. Unlike treatment limited to one location or modality or situation, this relationship will be multifactorial and ongoing. Furthermore, a privately operating care provider is likely to represent an entry contact point into mental health care. If the patient and the associated significant family members are not put at ease, their questions answered and concerns addressed, the contact may quickly end.

Older patients are often novices regarding mental illness and its treatment. They are often fearful of being thought "crazy" or of being "put away". Structuring the beginning of the initial interview can help relieve their anxiety. You may start with 10–15 min of specific questions, such as address, age, date of birth, concrete information on marriages, children, parents, siblings, education, employment, interests, etc. This can also give you a lot of information in a short time, helping to give a more complete picture of the patient. Simultaneously, you are assessing aspects of mental status and memory.

Treatment of the older patient includes the time when the patient is away from the office. The patient is helped when assured of the doctor's continued interest and care. This can often be done using relatively simple techniques: (a) providing specific information tells the patient that you know what is going to happen, e.g. "This medicine is going to take 2–3 weeks to build up in your system. You may experience some side effects during that period but you will not experience the benefit for 2–3 weeks. You need to be patient during that time"; (b) assuring access and inviting communication, e.g. "My telephone number is a 24 hour number. If you have any problems or need to reach me, you can call any time". Patients rarely do call outside of office hours after being told this, but they feel very reassured; (c) specific instructions for behavior and for contacts, e.g. instead of saying, "Call me if you have any problems", saying "Call me next Tuesday", assures the patient that you want to hear from him/her. It also reduces the number of calls he/she might otherwise make before next Tuesday.

FAMILY INVOLVEMENT

Families are often interested and involved in the psychiatric care of elders. Relatives and friends can be important sources of information to the doctor. Interactions may include mediation and other interventions into the family system, re-interpretation and re-framing of past and present events, support, reassurance and education. Attention to family issues is especially important in treatment of patients with dementing disorders[33,34].

Because of the increased interrelationships and involvements some families have in an older patient's status and treatment, it is often vital to maintain contact and a positive rapport with the family. Also, patients will often request this. Conversely, when family members feel unnecessarily excluded or denied access to information, they can influence or disrupt the treatment entirely. This is not to imply that therapeutic confidentiality is not maintained; families generally understand this. They do, however, want to know that appropriate help is being provided. Such reassurance can have a positive therapeutic effect on the patient, as a reflection of the family's confidence in the doctor. It can also have the practical influence/effect of helping to keep the patient in treatment.

In situations where there are no immediate relatives, non-kinship, support networks become increasingly important[35]. The therapist may at times utilize the assistance of family surrogates in gathering information and in helping the patient. Where such networks are weak or absent, assisting the patient in their creation can be of great benefit.

RELATIONSHIPS WITH OTHER PHYSICIANS

In the absence of the formalized organization of a university environment or the planned hierarchy of a hospital or corporate structure, the geriatric psychiatrist in private practice must create or seek out relationships with other practitioners. This can be done through involvement in professional societies, participation in the activities of the community's hospitals and through non-medical social contacts. Eventually, further relationships will also be created by patients who seek psychiatric services and request that contact be established with their other treating physicians. Collegial relationships thus created can provide advice and assistance, help in monitoring the status of patients between visits to the psychiatrist and provide sources of referrals for new patients.

RELATIONSHIPS WITH OTHER PSYCHIATRISTS

As with other physicians in general, private practitioners must create a network of relationships with other psychiatrists in the area, both near and far. Those at some distance, or whose special areas of interest or expertise differ, can be sources of referrals. Other psychiatrists may receive inquiries or have patients referred to them whom they are unable to treat; they may then direct them to you. Psychiatrists who practice in closer proximity may also be sources of new patient referrals, especially when their treatment interests differ from yours. Furthermore, a certain percentage of patients, especially those with chronic or recurring illness, may be "doctor-shoppers" and spontaneously, or by referral, change from one practitioner to another over a period of time. Developing good rapport with other local psychiatrists helps in providing better care to these patients by sharing understanding of their needs, pathology and past successful treatments and by helping to avoid duplication of previously attempted unsuccessful treatments.

Formal or informal groupings of private psychiatrists may gather for continuing education and study, to help with supervision, second opinions or "risk-management" of difficult cases, or to share tasks, such as psychiatric coverage for a local hospital's emergency room. When a private practitioner takes a break, to go on vacation or to a conference, it may be one or more of these local psychiatrists who is asked to be available to take care of emergencies or to provide ongoing services to patients who are hospitalized at the time. Often such favors are done reciprocally as a courtesy.

RELATIONSHIPS WITH OTHER PROFESSIONALS

Other professional care providers with whom privately practicing geriatric psychiatrists and their patients come into contact include psychologists, social workers, nurses, speech therapists, occupational therapists, hospital administrators and the operators of nursing homes and congregate-living facilities. Knowledge of these and other community resources is essential for the geriatric psychiatrist. At times the best treatment offered to a patient may

be a referral to one of them. Needless to say, each of these can provide valuable services. As they get to know the geriatric psychiatrist, they can also be valuable resources, e.g. they can be excellent sources of information about a patient's status and functioning when the patient is not in the doctor's office. They may allow the psychiatrist to provide more and better service to patients by helping to monitor, care for and carry out treatments with the patient. They can alert the doctor when problems are developing, often earlier than the patient might have, and can assist in the management of a crisis by supporting and reassuring the patient. These individuals are sources of referral to the practitioner. They will also speak to others in the community of their experiences and contacts with the practitioner. This is an important facet of how a professional reputation is made.

RELATIONS WITH HOSPITALS

Each psychiatric program within a hospital can have its own rules, regulations, standards, patterns of practice and pattern of relations with community-based practitioners. Some hospital facilities employ psychiatrists on staff; others may not. Some programs are organized more in accord with the direction given by the hospital and the hospital-based staff. Others encourage more involvement in program planning by the community staff physicians. Some facilities are sites for training programs and have psychiatric residents who provide services. There are some geriatric facilities within free-standing psychiatric hospitals and others that are geriatric units within medical hospitals; some are located in private, for-profit hospitals, or in non-profit or public or charitably-funded institutions, or in university-affiliated programs. While the rules, staffing patterns and required paper forms may vary from hospital to hospital, these variations are, for the most part, not so onerous as to be unworkable or impossible to deal with for the community-based practitioner. In some of these settings, the community-based practitioner may be able to influence the nature of the hospital's policies and treatment program by participation in psychiatric departmental meetings and activities.

The differences among hospitals requires some flexibility on the part of the doctor, but also may allow the possibility of tailoring referrals to the hospital most appropriate to the patient. For a variety of reasons, different hospital units acquire different patient populations and characteristics. Some programs are age-segregated, with specifically designated geriatric psychiatry wards. Others are age-integrated, with younger and older patients sharing and participating in the treatment program together. Some programs may be more suitable for cognitively intact, physically healthy older people suffering from affective or anxiety disorders or relationship dysfunctions.

THE POSSIBILITY OF INPATIENT HOSPITAL TREATMENT[36]

At the time of the initial visit or at some subsequent time in the course of the treatment of an older patient, the psychiatrist may recommend inpatient hospital treatment. The process begins with an assessment of whether the hospitalization is something that would be beneficial and therapeutic but non-emergent, or is an urgently needed admission due to imminent danger to the patient or others. Immediately after this decision, the psychiatrist must decide whether the patient is capable of consenting to this plan. Depending upon the hospitals and resources available in the community, these assessments may lead to a decision to use a particular inpatient facility. For example, there may be one that can admit people on an involuntary basis, or care for people who are potentially suicidal or aggressive. Similar choices may result from the ability of a specific hospital's psychiatric ward to care for elderly patients who have concurrent severe medical problems, or who are wanderers, or who need the hospital's specific therapeutic approach. Other factors that affect the choice of inpatient service include locations of past hospitalizations, the hospitals used by the patient's other treating physicians, proximity to the patient and the patient's family to allow for visitation and, importantly, whether a particular hospital has a room available for the patient at the time it is needed, and whether the admission can or can not be delayed until a bed becomes available. In some cases, where room is not available locally or at the time needed or where local facilities are not appropriate, referral for hospitalization may have to be made to a psychiatrist or facility elsewhere.

ADMISSION TO HOSPITALS

Various hospitals and psychiatric facilities within hospitals may have different procedures for arranging admissions. Typically, the psychiatrist communicates with a designated person or office to make the reservation for admission. Information that must be provided at this point varies but usually consists of the patient's name, age and admitting diagnosis. Some facilities may also wish information regarding the geriatric patient's ability to function in activities of daily living, mobility, signs and symptoms of the patient that warrant admission, a preliminary treatment plan, or the likelihood of the patient being a danger to self or others.

When the patient is admitted, each hospital's usual procedure begins. Administrators and nurses fill out forms. The patient is shown to a room, belongings are put away and the staff makes the patient acquainted with the facility and program of activities. At about the same time, the private psychiatrist is notified that the patient has arrived. If not already given, initial orders are requested. When the psychiatrist is not available to come to the hospital immediately, orders might be given by telephone to the ward nurse, addressing such needs as diet, monitoring of vital signs, laboratory tests, ward therapies and medications to be started, etc.

IN-HOSPITAL TREATMENT[36,37]

In-hospital treatments for the elderly can include the full spectrum of therapeutic approaches devised for psychiatric patients in general, although these might vary depending upon the resources and philosophy of the facility and the specific instructions of the doctor. The psychiatrist may personally provide individual psychotherapy, family therapy, psychotherapeutic medication management, electroconvulsive therapy, or other treatments, as well as ongoing diagnostic evaluation. Many older patients also benefit from group, occupational, recreational and ward milieu therapies, physical therapy, speech therapy or reality-orientation/memory-stimulating techniques. Often, the community psychiatrist is not directly involved in these treatments; the hospital's staff members provide them as part of the hospital's program and report back to the doctor regarding the patient's progress. Nurses, social workers and other staff members also inform the psychiatrist about the patient's status, symptoms, behavior and reactions to treatment as observed during the day. Coordination, mutual understanding of achievable goals, cooperation and respect between the psychiatrist and the hospital administration and staff facilitate the psychiatrist's functioning and the treatment of the patient. It is vital that a good working relationship be achieved. If it is not, the doctor can be undermined in numerous ways.

Working in the hospital requires flexibility on the part of doctors and staff. The staff must accommodate to various

physicians and their styles of treatment. The doctors must adapt to the hospital and its program, including its staffing pattern, its treatment approach and its physical plant. Patients may be seen at times under less than ideal conditions, including differing circumstances, locations, times and schedules (e.g. seeing a patient in a semi-private room, planning hospital rounds to not conflict with group therapy programs, visiting patients only to find that they are in physical therapy or getting X-rays).

POST-HOSPITAL TREATMENT

Planning for hospital follow-up begins during the hospital stay. The physician can direct the social service worker regarding possible directions and options for such problems as living situation changes, needs for at-home services, assistance or care, possible adult congregate-living facility or nursing home placement[38]. The social worker can investigate these and coordinate planning with the physician, patient and patient's family. Other post-discharge options the doctor can order include visiting nurses, physical therapy and other home health treatments or referral to a senior day center or a partial hospitalization day program[39,40]. The patient's needs, desires, finances and therapeutic considerations (including the options for follow-up treatment with the psychiatrist) are important factors in these choices. Similarly, the available, involved members of the family may have opinions or suggestions. They may also direct the psychiatrist's attention toward additional problems or issues they feel are significant.

An important part of discharge planning is the re-engagement of the patient in outpatient treatment in the psychiatrist's office. An appointment can be given at the time of discharge or the patient may be instructed to make an appointment within a specified period of time. The psychiatrist makes certain that needed hospital records, including discharge summary, list of discharge medications, copies of laboratory and radiograph reports and medical consultation reports, are sent to the office. This enhances completeness and continuity of care.

In addition to other usual psychotherapeutic issues that can be discussed in the post-hospital treatment, it is important to include a review of the patient's reactions to the hospital, the symptoms that necessitated the admission and the patient's progress there. Also, it is important to watch for post-hospital regressions and symptom recurrences, as the patient returns to his/her usual surroundings or to a new environment. Medication compliance and monitoring is another post-discharge task that requires attention, especially if the medication is new, if it is causing some side effects or if it requires special care in its use (e.g. special diet or times of administration).

CONCLUSION

Community-based ambulatory psychiatric care is a relatively young and growing avenue for the treatment of older adults in the USA. There have been relatively few specific models of private psychogeriatric care described to date. Aspects of the treatment of younger adults in the community are being applied to the care of seniors; however, modifications are important in order to more fully address the special problems and needs of this population.

The Psychiatrist's Role in Linking Community Services

Deirdre Johnston, Kimberly A. Sherrill and Burton V. Reifler

Wake Forest University School of Medicine, Winston-Salem, NC, USA

In addressing the mental health needs of older adults in the USA, psychiatrists are faced with a number of significant challenges. One of them remains sheer demand: the number of patients needing services still outstrips the availability of psychiatrists, especially those with specialized geriatric training. A second challenge is that of collaborating effectively with the primary care sector who, as will be described in some detail later, provide mental health care for the vast majority of the elderly. Third is the challenge of understanding and working effectively with a wide range of non-physician providers of services to older adults. These and other difficulties will likely become more pressing as the demographic trends towards an older society are accompanied by increasing financial restrictions.

Many psychiatrists are responding to these challenges by enlarging their role from that of generalist clinicians to geriatric-specific educators, academicians and researchers, as well as sources of expertise for innovative community-based programs. We will begin by documenting the need for services, alluded to above, and follow with examples of how those role changes are being manifested in important new programs and initiatives. We conclude with comments on future directions for the psychiatrist's role in the process of change, and a discussion of some of the premises underlying the current system of mental health care for the elderly.

THE NEED FOR MENTAL HEALTH SERVICES AMONG THE COMMUNITY-BASED ELDERLY

One way to estimate the current need for mental health services among the community-dwelling elderly is to take the prevalence rates of mental illness and subtract the portion of those already receiving services. In terms of prevalence rates, the elderly appear to have rates of mental disorders about the same as those of younger adults[1]. One of the more conservative estimated prevalence rates for lifetime psychiatric disorders, 12.3%[2], comes from the Epidemiological Catchment Area (ECA) study, while another recent community-based study documents a higher rate of 31%[1].

Using specific and fairly restrictive criteria, Shapiro *et al.*[3] estimated from ECA data that some 7.8% of those aged 65+ need mental health services. If the ECA study results can be generalized to the population as a whole, and given that the vast majority (99.6%) of the nation's 29.8 million adults aged 65+ reside in the community rather than in institutional settings (US Census Bureau statistics, 1987), then some 2.3 million community-residing elderly may be said to need mental health care.

Many of those needing services are not seeing a mental health professional. In Goldstrom *et al.*'s Bunker Hill study[1], among patients aged 65+ with a psychiatric disorder, only 42% had at least one visit to a mental health professional, compared to 68% among the 18–44 age group ($p < 0.01$) and 53% among the 44–64 age group ($p < 0.01$). Shapiro *et al.* calculated that 5.7% of the total population of elderly need, but are not receiving, mental health services. About one-third of those needing mental health services are being seen by the specialty mental health sector, another one-third receive care only from general medical care providers, and the other one-third receive no care[2]. Recent evidence suggests that considerable barriers still exist in the public sector that prevent the elderly from receiving specialized psychiatric care[4]. The elderly have tended to be slow to report psychiatric symptoms compared to younger adults[5].

The fact that so many patients with *mental* health needs are being seen by the *general* medical sector (the "*de facto* mental health system")[6] is important for several reasons. Numerous studies document that primary care practitioners overlook psychiatric disorders in their patients[7,8], and, even when treating patients for mental disorders, tend to do so inadequately[9]. It has also been suggested that physicians may misinterpret somatic markers of depression as being due to physical illness[10]. In the USA, an increasing number of older adults are enrolled in managed care plans, which usually require that the primary care physician treat most uncomplicated illnesses, limiting access to specialist care. Recent evidence suggests significant differences in the treatment of older people with depression enrolled in health maintenance organizations (HMOs) compared with younger depressed patients. Older patients received fewer mental health specialty visits, fewer prescriptions for SSRI antidepressants, and were more likely to be prescribed benzodiazepines[11]. As the managed care model expands nationwide, the evidence remains that the depressed elderly are underserved[12]. Thus, there is a great need to train primary providers in the detection and treatment of mental disorders. Also, geriatric patients with mental disorders make twice as many office visits to their primary care providers as do those without a mental disorder[1]. If those patients received adequate treatment, then according to the so-called "cost-offset" hypothesis, the improvement in mental health would result in substantial decreased utilization of other health care services, thus "offsetting" the expense of providing mental health care[13,14]. Investigators estimate that treatment for mental disorders is accompanied by an overall 20% decrease in the use of general

healthcare services, especially for inpatient care[15,16]. In a climate of fiscal restrictions, such information lends needed support to the value of adequate mental health care.

CLINICIANS AS GERIATRIC SPECIALISTS

The tremendous need for expertise in caring for geriatric patients has been part of the impetus for the evolution of geriatric psychiatry into fully-fledged subspecialty status. The American Association of Geriatric Psychiatry was founded in 1978. Recognition as a subspecialty came with the administration of the first examination for added qualifications in Geriatric Psychiatry in April 1991 by the American Board of Psychiatry and Neurology. By 1999, 2360 psychiatrists had passed the examination and there were 39 ACGME-accredited geriatric psychiatry fellowship programs nationwide.

Becoming a geriatric specialist in psychiatry involves assuming a unique constellation of familiar roles, rather than some distinctive singular role. Diversity is the hallmark of the team membership roles geriatric psychiatrists are called upon to assume. Examples of that diversity include coordinating clinical care, taking part in community initiatives and participating at various levels in educational activities.

CLINICAL ROLES

Clinical care has evolved to a model that is much more comprehensive than before, with an emphasis on multidisciplinary assessment. One successful model for a geriatric assessment clinic originating in Seattle[17] included a psychiatrist, an internist and a social worker. The assessment took three to four clinic visits, one for each of the following: (a) a psychiatric evaluation; (b) a medical evaluation; (c) a home visit; and (d) a family conference at the conclusion of the evaluation, for discussion of results and recommendations. When the patient suffered from cognitive impairment, the model often included neuropsychiatric assessment.

The Seattle clinic demonstrates the emergence of a common theme that has become the standard for comprehensive geriatric assessment: a focus on the patient's psychosocial context. Families of geriatric patients have attracted much interest since the emergence of the subspecialty of geriatric psychiatry, because of the critical role they play in the care of demented elderly patients. While attention to families has always been characteristic of certain areas within psychiatry, notably child psychiatry, until the notion of comprehensive geriatric assessment was developed, families of psychiatrically ill geriatric patients were considered ancillary, rather than integral to patient care. A major catalyst behind this broadened perspective has been a large body of research, which demonstrates the vital role of psychosocial issues for the health and well-being of older adults[18,19]. In recent years, research has focused on the mental health of caregivers and caregiver factors influencing service utilization and institutionalization[20,21].

Other innovative programs have been described, e.g. Bienenfeld reported on a liaison service to nursing homes[22] and Reifler *et al.* described an outreach program for mentally impaired older adults in Seattle[23]. However, although it is by now well established that there is a high prevalence of psychiatric morbidity in nursing homes, there remains a great need for psychiatric consultation in this setting. Legislation limits the prescription of psychotropics in US nursing homes in order to prevent the use of "chemical restraint", and pharmacists conduct periodic reviews to ensure compliance with these rules. One innovation that may enhance psychiatric involvement in the care of nursing home patients is video teleconsultation, which enables the psychiatrist to interview patients at remote locations, usually with the nurse in attendance on the patient. Research to date suggests that this can be an effective and economically viable medium[24].

COMMUNITY ROLES

Social service agencies, nursing homes, local Alzheimer's Associations, home healthcare organizations, hospice care and other organizations that coordinate services for the elderly are eager for psychiatric expertise. Collaboration also allows geriatric psychiatrists to become well acquainted with available resources and to learn when to refer to such organizations. An incentive for the development of innovative community-based programs is the increasing cost of long-term care.

One example of innovative community-based care that has begun to involve geriatric psychiatrists is the adult day center (ADC) movement. The idea of ADCs actually evolved from the mental healthcare system, where day programs had been utilized for some of the more seriously ill psychiatric patients who needed greater support than could be provided by periodic outpatient clinic visits. Adaptation of that notion to the needs of geriatric patients began to appear in the mid-1970s and early 1980s, and the movement mushroomed from only 15 documented ADCs in 1975 to over 4000 by 1998[25].

The Robert Wood Johnson foundation initiated a national demonstration project (the Dementia Care and Respite Services Program) in the late 1980s to promote further growth of dementia-specific ADCs. One of the primary goals of the project was to determine whether centers could become financially viable through charging for their services. Centers had struggled with unstable financial bases, which depended on their ability to obtain grant support or contributions or to utilize transient state and federal funds. The 4 year program began funding for 19 model ADCs in 1988[26]. The "Partners in Caregiving" initiative, which included the initial 19 sites and a subsequent demonstration program involving 50 sites across the USA, showed that adult day care centers could care for individuals with all degrees of dementia, from mild to severe, while remaining financially viable by meeting over 80% of their expenses through out-of-pocket payments and Medicaid[25].

Other community-based models involving psychiatrists have developed. Robinson[27] reviewed four of them, including: (a) the Channeling Demonstration, a federally-funded initiative awarded to 12 states, designed to serve severely impaired elderly people at risk of being institutionalized and to test two types of case management; (b) the Social/Health Maintenance Organization (S/HMO), a concept developed by Brandeis University, which is a managed care system of health and long-term care; (c) the On Lok Senior Services Program, a consolidated group of medical and support services based in San Francisco; and (d) Life Care Communities, which include some 600 continuing care communities nationwide, as well as the case-management delivery system called "Life Care at Home". The Channeling Demonstration, while it did not save money, did improve quality of life for clients and caregivers. The S/HMO model achieved its goal of integrating the funding and social services of long-term care, but did not succeed in integrating medical and social services or utilizing geriatric specialists[28]. An updated series of HMOs ("S/HMO II") has begun, which have pledged to incorporate professionals with expertise in geriatrics into the range of services provided. The On Lok model, now known as the Program of All-inclusive Care for the Elderly (PACE), has been replicated in dozens of cities around the USA, with almost 3000 enrollees nationwide. Participants average 80 years of age, and have seven or eight medical conditions. All of their health care is provided by a PACE interdisciplinary team. Outcome studies are under way. So far, the

program has been shown to lower hospital and nursing home utilization costs, and most of the patients fared as well as or better than predicted, based on their baseline clinical status[29].

EDUCATIONAL ROLES

Many psychiatrists have responded to the acute need for geriatric-specific services and education in the community by conducting workshops and seminars for professional groups and providing consultation for various organizations. However, a response that provides for community needs for a long-term perspective is to teach geriatrics to medical students. A 1978 Institute of Medicine report urged medical schools to incorporate teaching related to aging in both the basic and clinical sciences. In 1993, the Institute of Medicine Committee on Strengthening the Geriatric Content of Medical Training convened to assess the status of geriatric training and to develop recommendations on strategies for improving the training of physicians in geriatrics[30]. It found a decline in the number of applicants for funded fellowship programs in geriatric-related specialties. It also found that the number of geriatric faculties in all specialties nationwide was insufficient (and in psychiatry by 1221 positions) to meet the training needs of all undergraduate medical students and residents. In response to this report, the John A. Hartford Foundation initiated a project to "Integrate Geriatrics into the Subspecialties of Internal Medicine". Recognizing that the majority of the teaching of medical students and residents is performed by those in the medical subspecialties, this initiative was designed with the goal of raising awareness and competence of the medical subspecialist in the care of the elderly.

This 6 year, $3.5 million project has sought to identify leading subspecialists, to redirect their attention to the subtleties of geriatric aspects of their discipline, and to ascertain opportunities for teaching and research within those aspects. The primary vehicle for this is the Geriatric Education Retreat (GER), a 5 day gathering of leaders in the subspecialty and geriatricians[31]. As a result of this project, nearly every national medical organization has added a symposium to their annual meeting, focusing on geriatric aspects of the discipline; fellowship training curriculum is being developed within half of the identified subspecialties; the residency Review Committee of Internal Medicine has added the requirement that all fellows must have substantial experience with patients aged 70+, and the American Board of Internal Medicine has recently adopted a "cross-content" blueprint for all examinations, which includes internal medicine. An essential curriculum in geriatric psychiatry for general internal medicine residents and geriatric medicine fellows has been described[32]. The Foundation has provided an extension grant to convene a GER for the specialties of Neurology and Psychiatry with the goals of "gerontologizing" the practicing neurologist and psychiatrist and infiltrating the curriculum of the residency and fellowship programs with the knowledge needed to provide competent geriatric care.

CONCLUSIONS

Several important areas of need, and examples of efforts to respond to them, have been discussed briefly in this chapter. In summary, although progress has been made in training general psychiatrists and other specialists in the care of the elderly, there remains a need for psychiatrists to improve their ability to diagnose and treat psychiatric disorders in the elderly; to participate in improved training in geropsychiatry for primary care physicians as well as for other mental health professionals; to participate in developing innovative new models of service delivery; and finally to be willing to enter research and academic careers with a focus on geriatrics[33].

Goldman and Frank[34] noted that addressing the needs listed above are particularly difficult, given the emphasis on cost-containment and efficiency prevalent today, in contrast to the mood of equity and access to care that was characteristic of the 1960s. Indeed, critics of the current approach to geriatric psychiatry state that the system is problem-driven, evolving in a way that is reactive to economic, political and social forces. They argue that a prevention-driven system is needed, which springs from more proactive efforts, anticipating needs and attempting to respond to them in light of available resources.

Several premises that underlie mental health care for the elderly in the USA were set forth by Burns and Taube[2] and may help to explain the rationale behind the evolution of our current system: (a) there is a preference for providing care in the community instead of institutions; (b) there is a belief in the value of managed care approaches, such as the use of case managers and primary care physicians as gatekeepers to the mental health system, and organizations such as HMOs and preferred provider organizations; (c) there is a preference for service provision general providers instead of specialists when feasible; and (d) there is a belief that care should be comprehensive, continuous and of high quality.

There are, of course, many other needs that are beyond the scope of this chapter, such as those dealing with economics, health policy and political considerations. Nevertheless, there is a great potential for positive change if the basic problem areas listed above can be satisfactorily addressed.

The Medical Psychiatry Inpatient Unit

David G. Folks[1] and F. Cleveland Kinney[2]

[1]*University of Nebraska College of Medicine, Omaha, NE, and*
[2]*University of Alabama School of Medicine, Birmingham, AL, USA*

Medical psychiatry inpatient units primarily serving older adults have increased in popularity and numbers in North America in recent years. Several model programs have been described with respect to structure and organization, clinical care and logistical advantages in the management of older psychiatric patients who suffer from significant medical and surgical problems. The literature also suggests that medical psychiatry inpatient units offer great advantages over traditional settings in the diagnosis and treatment of elderly patients with combined disorders. Older psychiatric patients with acute medical illness, chronic medical conditions, the negative physiologic and psychologic concomitants of ageing, the problems of polypharmacy, drug interaction and compliance, together with the need for a more comprehensive and effective clinical approach, have culminated in a number of refinements in these units. The senior author's own experience in developing, organizing, operating and continually evaluating a dynamic geriatric medical psychiatry program lends support to the importance and utility of this treatment modality. This chapter will review in detail the structure, organization and clinical characteristics and financing of a medical psychiatry inpatient unit.

STRUCTURE AND ORGANIZATION OF THE GERIATRIC MEDICAL PSYCHIATRY INPATIENT UNIT

The medical psychiatry inpatient unit is generally orientated towards the admission and treatment of patients with combined medical and psychiatric illnesses. An attempt is made to integrate medical and psychiatric care, utilizing a biopsychosocial or systems treatment approach. The unit itself may be influenced by the administrative structure of the facility, the orientation of the medical and psychiatric community, the priorities among the clinical and administrative leaders and/or the general resources and expectations of the population to be served. Young and Harsch[1] alluded to three guiding principles that must be met in order for a medical psychiatry unit to succeed. These are the following: (a) the provision of a distinct type of care; (b) an improved quality of care; and (c) more efficient care. Another primary consideration in North America is the need to demonstrate that added costs to third-party payers and hospitals will yield greater benefits for both the patient population and the medical facility. The financing of these units with respect to changes in the USA are to be addressed in this chapter.

The medical psychiatry inpatient unit maintains a distinctive patient population by virtue of admission criteria. Patient characteristics may also be determined by affiliation with various governmental or community agencies, or perhaps by other referring psychiatric facilities that are unable to provide care for medically ill psychogeriatric patients. Of course, healthier psychiatric patients may also benefit from the medical model adopted in a medical psychiatry unit. However, these units truly provide a therapeutic edge and hold promise for the successful clinical approach to a growing number of seriously medically ill or functionally compromised elderly psychiatric patients[2]. Furthermore, the work-up and treatment may potentially be performed without major increases in length of stay. Incidentally, these units are known to provide an excellent milieu for clinical training in psychiatry and other disciplines.

The ideal physical environment of a medical psychiatry inpatient unit ensures safety for delirious or behaviourally disturbed elderly patients, facilitates the rendering of medical services, and provides a pleasant environment suitable for relatively long hospital stays. The overall space requirements do not differ markedly, but do exceed the space ideal for general hospital or free-standing psychiatric units. Presumably, the facility contains essential equipment and structure that would not otherwise be found on a psychiatric unit; the level of care delivered could, therefore, not be provided, or provided as well, on the "typical" psychiatric unit. This inpatient approach is in contrast to the consultation–liaison model of managing medically ill psychiatry patients on existing medical/surgical wards.

Features of patient rooms in a medical psychiatry unit may vary depending on the individual characteristics of the patients. Essential safety features include shatterproof windows, breakaway curtain rods, electrical outlets that disconnect in response to tampering and lockable water taps, especially with semi-private baths. Certainly, for medically acute patients, lighting for bedside examination, outlets for oxygen and suction and adjustable hospital beds are necessary. A voice-call light system, a facility for glucose monitoring and availability of cardiac telemetry are highly desirable. Medical psychiatry inpatient units are also expected to provide care for patients requiring intravenous fluids/therapy or nasogastric suction, who need total care in a bedridden or debilitated state, as well as oxygen support or clinical management of common medical conditions, e.g. diabetes, hypertension, angina, congestive heart failure, chronic pulmonary disease, electrolyte or fluid balance disturbances, and urinary tract or pulmonary infections. Patients with great acuity may be too labor-intensive, i.e. the ideal unit should be designed to strike a balance between the provision of basic medical care and the provision of intensive psychotherapeutic care. The ideal unit will also consist of patient rooms that are largely private, but some

therapeutic benefits may be derived from semi-private rooms for patients who are withdrawn, or for cases in which a higher-functioning roommate can provide aid to another with respect to orientation and structure. All patient room entrances and bathroom facilities should be wheelchair-accessible. An emergency cord should be available in the bathroom and should be reachable from the floor by patients who may have fallen. The same architectural suicide prevention considerations found on general psychiatric units should be built into the medical psychiatry inpatient unit. Other needs include shower and patient-lifting devices, a bedside weight scale, suitable chairs, supply facilities/cart and, more controversially, mechanical (soft) restraints and effective methods of observation.

The unit ideally will include built-in handrails along the walls, television facilities for bedridden patients, and industrial-grade carpet to soften falls in the hallways and/or common or public areas but with vinyl to facilitate cleaning in patient rooms. Patient rooms are designed to maximize observation and minimize noise that may distract the staff. Finally, consideration must be given to whether a medical psychiatry unit will be locked, closed or controlled, and whether involuntary patients will be admitted. With adequate numbers of trained staff, it should not be necessary to have barriers to free movement. Where sufficient trained staff cannot be provided, some units have double-handed doors. The controlled unit, utilizing electronic beep or entry computer codes, ensures that wandering by cognitively impaired patients can be thoughtfully controlled. The locked or controlled-access unit provides both safety and containment. Separate areas are designed for activities and occupational or physical therapy.

The flow of staff and consultants tends to be great on a medical psychiatry unit; thus, workspace is an important consideration. Nursing units may be better divided into modular work stations with built-in cabinetry and shelving. The record and medication room can be separated by a locked door and the entire nursing station designed as an enclosed area with an observation/reception window made of safety glass. Sufficient storage space for medical equipment and supplies should also be considered. The care of complex, medical–psychiatric patients often requires frequent, small conferences among professionals of different disciplines and specialties in order to coordinate care. On-site professional offices for the medical director, social worker, head nurse and trainees afford privacy and a quiet environment for conferences and interviews. Preferably, physical therapy should be provided on-site if at all possible; a physical therapist permanently assigned to a medical psychiatric unit may incorporate psychiatric skills into the therapy treatments and may become an integral part of the treatment team. In addition to common areas for group dining, activities, educational programs, family meetings, group therapy and occupational therapy, additional space is necessary for staff meetings and conferences. An adequate staff lounge not only improves morale but also facilitates communication between the healthcare professionals and multidisciplinary personnel.

OPERATIONAL FEATURES OF THE GERIATRIC MEDICAL PSYCHIATRY INPATIENT UNIT

A multidisciplinary treatment team is generally assembled in order to address the complex needs of geriatric patients with combined disease. Each member contributes to the administration and operation of the unit, and each discipline contributes uniquely. A nurse clinical specialist with both medical and psychiatric experience may act as a milieu coordinator/supervisor for the nursing staff. Complex social work interventions require great expertise in family consultation, assessing hospital and community services and providing assistance in disposition. Consulting psychologists with experience in neuropsychology, personality assessment and behaviour therapy are invaluable team members. The nursing staff should consist primarily of registered nurses combining medical–surgical and psychiatric skills. Practical nurses and nurses' aides can participate in the delivery of care and may also become adept in the clinical care of combined medical–psychiatric problems. Senior nurses with extensive psychiatric experience often contribute greatly to the management of behaviourally difficult patients. Irrespective of experience and background, nurses who enthusiastically support the model of combined medical–psychiatric care are ideal. Above all, the nursing staff must possess flexibility and resourcefulness combined with a practical and optimistic approach, in view of the constant changes in demands.

The usual format for the medical psychiatry inpatient unit in North America employs a model in which a psychiatrist or internist acts as an attending professional, experienced in directing a team and communicating with both mental health professionals and medical–surgical professionals. The medical director is responsible for gatekeeping, quality assurance, staff supervision, training, in-service education, trouble-shooting and the provision of consultation (directly or indirectly) in difficult cases. Liaison with community agencies, public affairs and assistance with legal and ethical problems in patient care are also required of the medical director. Administrative interfaces with the affiliated department, hospital, community mental health center and referring resources are essential. These interactions will vary according to the individual orientation and characteristics of the facility. Similarly, other third-party, legal and governmental interactions will vary accordingly.

CLINICAL AND PATIENT CHARACTERISTICS OF A GERIATRIC MEDICAL PSYCHIATRY UNIT

A variety of patient subtypes may be considered appropriate for an inpatient medical psychiatry unit. Three patient subtypes have been identified by Stoudemire and Fogel[3]: (a) patients with severe medical illness requiring daily medical coverage in addition to treatment of psychiatric illness; (b) psychiatrically disordered patients who require frequent but not daily medical attention from a surgeon or internist, e.g. diabetic or post-surgical cases; and (c) patients who merely require an initial consultation or periodic access or review/adjustment of medications by a medical consultant. Depression in the medically ill, chronic schizophrenia with concurrent physical disease, i.e. stroke, epilepsy, Parkinson's disease, head trauma, delirium, complications of dementia, or paroxysmal behaviour disorders, and a variety of other general medical illnesses with complex family or psychosocial issues, characterize appropriate cases for admission and treatment.

The average length of stay on a typical unit is generally approximately 7–21 days. Site-specific considerations pertaining to the selection of appropriate patients must be analyzed in order to determine specific inclusion and exclusion criteria. A well-defined priority system can then be established in order to determine which patients are admitted or provided with access to care. Regarding admission, patients on affiliated medical/surgical wards, and cases seen by the emergency or staff physicians, are typically given special consideration. Above all, patient acuity, dispositional resources and the staffing will determine the answers to many gate-keeping decisions. Moreover, the primary mission of these units remains the provision of psychiatric care to individuals who also have significant medical/surgical illness. Again, these patients are often *not* welcome in either traditional psychiatry or medical/surgical units. Finally, decisions regarding admission or transfer of inpatients from medical/surgical units may depend on the likelihood that the patient will receive true benefit, respond to

psychiatric treatment or require close observation in order to achieve diagnostic or therapeutic results.

Patients with general medical problems associated with psychiatric disturbances are challenging with respect to clinical management. However, several studies have implied that patients treated on such a unit benefit with respect to improved quality of care and shorter length of stay[4]. Medical psychiatry units are also more likely, compared to traditional units, to benefit patients with functional or cognitive impairment. For example, patients with coexisting dementia and depression are much more effectively addressed in a shorter time frame, with resultant decrease in length of stays, compared to those patients treated on a general medical unit[5,6]. Moreover, treatment in the medical psychiatry unit with aggressive outpatient follow-up may obviate the need for nursing home placement[6]. Primary interventions on a medical psychiatry unit may include pharmacologic or somatic therapies, as well as ongoing efforts to optimize the patients' general medical/physiologic status. Coping with illness, issues relating to loss and self-esteem, feelings toward a caregiver and social changes are other important psychotherapeutic themes commonly addressed in a geriatric medical psychiatry unit. Medical emergencies, e.g. cardiac arrest or status epilepticus, must be considered and anticipated. Emergent symptoms of delirium may also need attention and in these cases, the legal doctrine of implied consent applies.

PROBLEMS, ADVANTAGES AND CAVEATS WITH GERIATRIC MEDICAL PSYCHIATRY INPATIENT UNITS

The quintessential factor that determines the success of a medical psychiatry inpatient unit is *nursing care*. Ideally, nurses recruited from medical/surgical units or critical care areas who are keenly interested in psychological dimensions of patient care, are considered best-suited to the medical psychiatry inpatient unit. Professional attire and more traditional uniforms often help to minimize confusion about the medical role of the unit. Non-psychiatric nurses may be useful in order to update and maintain medical skills of the staff, and serve to maintain familiarity with newer techniques of intravenous therapy, oxygen therapy, suction and skills in cardiac monitoring, respiratory care and postsurgical care. Because nursing is the critical element in the successful operation of these units, appropriate head nurses are invaluable and a difficult resource to obtain.

Reimbursement and financial integrity are long-standing issues with the medical psychiatry unit[7]. For example, in the USA, the Tax Equity and Fiscal Responsibility Act (TEFRA) of 1982 has determined payment for services in psychiatric units. The Balanced Budget Act (BBA) was passed by Congress in 1997 and has replaced the TEFRA of 1982. This has resulted in a reduction of approximately 7–8% in revenues for care provided in a psychiatric unit. However, patients with concurrent medical and psychiatric illness may add an average of 40% to the annual cost of health care when compared to patients without concurrent medical and psychiatric illness[8–10]. Thus, psychiatric programs in general hospitals catering to the medically ill psychiatrically disordered patient are progressively less able to meet financial goals, because of the costs of ancillary medical service utilization, and free-standing psychiatric hospitals are also unable to include these patients in their patient mix. On average, psychiatric facilities are already losing money when they treat patients with combined medical–psychiatric illness[11]. Further, under the Balanced Budget Act, facilities in the USA stand to lose an additional 12% or more on such cases.[12]

Medical psychiatry units in the USA that pride themselves on the ability to treat complicated geriatric patients with co-morbid illness must consider the need to take immediate steps that will allow them to remain fiscally solvent. Further limits on admissions with no medical co-morbidity, or preference to patients with low psychiatric acuity, are the easiest solutions. However, these solutions do not allow the medical psychiatry inpatient unit to respond to the clinical needs of the complicated, high-cost co-morbid patient. A more satisfactory solution to this problem has been suggested by Goldberg and Kathol[11]. Specifically, a partnership among medical/surgical professionals, hospital administration and psychiatric departments is suggested. A model of providing full psychiatric care, yet billing to general medical reimbursers, is recommended, allowing higher reimbursement of *per diems* through medical service billings that are adequate to cover the costs of medical tests and procedures typically not included in psychiatric or behavioural health payments. Such service integration can be done in such a way that units can actually cover direct costs and make significant contributions to the indirect costs in healthcare systems, while improving care[13]. This is particularly true if general medical patients at high risk for, or demonstrating, psychiatric co-morbidity with high healthcare utilization are targeted for admission. When this is done, costs savings for such patients accomplished through shortened length of stay can be as much as $4000 per admission[11,13]. Thus, it is possible to capitalize on the relatively higher reimbursement available with general medical admissions—even under the DRG system, which is also affected by the BBA, while continuing to address psychiatric difficulties.

The interaction of medical and psychiatric illness requires a unit organized in the fashion previously outlined. As forementioned, this approach allows treatment that assists the patient in moving toward recovery, with the development of policies and standards that document quality, improved outcomes and better attention for patients treated with medical psychiatry morbidity[14]. Under this format, the psychiatric unit director or consultant becomes involved in creating and finding ways to enforce these standards and adequate reimbursement to cover costs is achievable. Clearly, general hospital units will not be able to afford to provide psychiatric care for the medically ill, and medical psychiatric units under pressure from the Balanced Budget Act in the USA will require reorganization in order to contend with the facets of the prospective payment system introduced in 1999. Without a medical psychiatry approach, medical psychiatry patients will be scattered about the hospital, with practices that will necessarily lead to poorer quality and higher costs in the average medical setting. Hospital administrations in the USA will find that the impact on medical length of stay will create worse financial liabilities for the DRG reimbursement. Administrators therefore must continuously monitor length of stay, admission diagnoses, and dispositional plans, while maintaining a favorable prospective payment format. Direct care costs, indirect operating costs, recovery of costs, costs offset with reduced utilization, as well as other indicators of cost effectiveness, should be considered in the overall economic equation.[2] Mumford *et al.*[15] have reported that treatment in a medical psychiatry inpatient unit may resolve problems that might otherwise become chronic and more expensive. Generally, however, units must deny admission to certain patient types whose care would exceed the permissible stay, and units must not become a way-station for problem patients. Without strict and clear guidelines, the medical psychiatry unit may become clogged and ultimately result in denial of care to a more appropriate patient. Cost-effectiveness studies are clearly needed to clarify many of these fiscal issues.

Kathol[13] is of the opinion that many advantages of a medical psychiatry unit depend heavily upon the medical director. Perhaps the most convenient model employs collaboration between the medical director and a liaison internist or psychiatrist who

provides appropriate consultative care. Because the medical psychiatry unit as a treatment modality may increase the risk for loss of continuity of care or actual loss of follow-up, strategies for interim and longitudinal care should be carefully considered. A mechanism should be devised by the medical director for coordination of all clinical care following discharge. A distinct advantage of continuity of care after discharge from these units is the opportunity to assess the impact of psychological and psychosocial interventions among general medical populations.

CONCLUSION

The geriatric medical psychiatry inpatient unit could continue to be increasingly important as disproportionate growth occurs among the older population in North America (and Europe). An integrative model is essential in the delivery of care, preferably in a well-equipped setting that is organized to concentrate on the combined care of medical–psychiatric patients. These units are also quite useful in teaching and research programs, or in settings where large consultation–liaison psychiatry programs exist. Leadership provided by the medical director and head nurse, clearly articulated admission criteria and a well-organized multidisciplinary approach are all essential ingredients for a successful operation. Finally, as economic, social and scientific factors converge and shape geriatric psychiatry, the medical inpatient unit may prove to be an optimal setting for intensive, inpatient geriatric treatment.

The Psychiatrist in the Nursing Home

William E. Reichman

University of Medicine and Dentistry, Piscataway, NJ, USA

In the USA, nursing homes and other related long-term care facilities care for approximately 1.5 million persons annually. There are nearly 600 000 beds in these facilities across the country. While at any given time only 5% of the nation's elderly reside in these settings, up to 50% of citizens can expect to spend some portion of their lives there[1]. Over the past several years, many authors have described the impressive prevalence and vast array of psychiatric disorders complicating the care of nursing home residents. When dementia is included, rates of diagnosable mental illnesses have exceeded 80%[2–9]. The widespread use of psychoactive medications[10,11] and mechanical restraints[12,13] for the treatment of disturbed behavior in this setting has been well documented[5]. The National Medical Expenditures Survey in 1987 reported that 31% of nursing home residents had a non-dementia-related primary or secondary diagnosis of mental illness[14]. The principal psychiatric conditions that are especially noteworthy in the nursing home include dementia-associated behavioral complications, such as agitation[15], depression[16–18], anxiety[19–21], sleep impairment[22,23,29–31], psychosis[19,24–26] and substance abuse[27]. While the prominence of mental disorders in long-term care settings is now beyond dispute, in the USA, staffing patterns, staff expertise, environmental design and models of care delivery much more closely approximate subacute and chronic general medical care capabilities than thoughtfully conceived mental health services[9]. As a result, there is a great need to redesign the accessibility, structure and quality of psychiatric care in American nursing homes. Toward this end, this chapter will address the fundamentally important functions that may appropriately be provided by the psychiatrist in the nursing home setting.

THE ROLE OF THE PSYCHIATRIST

In the USA, contemporary training in general psychiatry emphasizes application of the biopsychosocial model to the understanding and treatment of mental disorders and behavioral symptomatology. This orientation is especially appropriate for accurately diagnosing and successfully treating the elderly nursing home resident, in whom there is often the co-morbid occurrence of physical, neurological, psychological and social contributors to disturbances of behavior. By virtue of their medical training, psychiatrists are uniquely qualified to integrate biological, psychological and social factors into a multidimensional treatment plan that reflects the full complexity of a given resident's behavioral symptomatology. Specifically, well-trained psychiatrists are potentially able to offer approaches to treatment that include recommendations for the appropriate use of a wide variety of psychoactive medications as well as psychological, behavioral and milieu-orientated therapies. Unfortunately, little is presently known about the availability of psychiatrists to consult or manage residents in nursing homes in the USA. Additionally, a paucity of services research has been done to assist healthcare planners to better understand the character, quality and quantity of those professional functions that are provided by psychiatrists working within the nursing home milieu. In most settings, it appears that psychiatrists assume a purely consultative role, in which the primary physician (internist or family medicine practitioner) orders medication and is responsible for the course of treatment. In other settings, full responsibility for the management of the resident's psychiatric treatment resides more definitively with the psychiatrist. The factors that determine the relative intensity and scope of the psychiatrist's role vs. that of the primary physician in any given facility are largely unknown.

In a recently published study, Reichman *et al.*[28] examined the availability, characteristics and perceived adequacy of psychiatric consultation in nearly 900 nursing homes throughout the USA through a mailed survey to the directors of nursing of these facilities. Results indicated that 38% of nursing home residents were noted to be in need of a consultation by a psychiatrist. The frequency of these services was rated as "adequate" by only half of these homes. Nursing homes in urban and suburban regions reported better availability of psychiatric services than those located in rural areas. Nursing homes with larger bed capacities were also more likely to receive a higher frequency of services by a consulting psychiatrist. In examining the perceived adequacy of the psychiatrist's functions, these specialists were noted by two-thirds of the facilities as adequately providing diagnostic and psychopharmacologic recommendations. However, advice regarding non-medication approaches to treatment (e.g. psychotherapeutic, behavioral or milieu interventions), staff support, staff education, and attending to occasional conflict between the staff of the nursing home and resident families were reported as inadequately provided by consulting psychiatrists. Overall, the results of this study suggest that, in nursing homes in the USA, the perceived need for services provided by psychiatrists is significantly greater than the level actually provided. Additionally, it appears that the nursing directors of these settings would welcome an expanded treatment role for psychiatrists in the care of their residents with mental illness and behavioral disturbances.

While a substantial amount of research remains to be done to identify best practices for the delivery of psychiatric services in nursing homes, it is clear that the specialty of psychiatry has a vital role. In many facilities, the template of consultation–liaison psychiatry is most appropriately applied. In this framework, the psychiatrist attends to the specific mental health needs of an

individual resident, while also focusing on the needs of the nursing home staff. Resident-focused interventions provided by a psychiatrist in this context include diagnostic clarification and leadership in the assembly of a multidimensional treatment plan. For most nursing home residents suffering from mental disorders, the best outcomes likely result from optimal diagnostic accuracy and treatment that includes resident-focused psychotherapeutic or behavioral approaches, thoughtfully selected pharmacology, and specific modifications of the resident's milieu.

The liaison functions so vital to successful psychiatric care in the nursing home are varied. Clearly, the psychiatrist can be an essential resource to help staff to understand better the complex phenomenology and multifaceted treatment of dementia and mental illness in their work setting. The psychiatrist is also ably prepared to assist staff in effectively identifying and successfully managing their own job-related stress. Importantly, psychiatrists are often appropriately called upon to assist a nursing home's clinical or administrative staff in resolving conflict between the facility and a given resident's family members.

SUMMARY

In many respects, the contemporary nursing home, despite its staffing patterns and physical structure, is in large part a long-term psychiatric residential facility. Little research has been done to adequately inform the character of the best psychiatric clinical practices in this setting. However, existing data in the USA suggest that the need for formal psychiatric services in nursing homes is significant and largely under-met. By virtue of their interest and training, psychiatrists are well-suited to work as members of a multidisciplinary care team in the construction and implementation of a multidimensional treatment plan directed at a resident's mental disorder. Additionally, through the established role of liaison, the psychiatrist can do much to foster an improved sense of well-being among nursing home staff.

Patient Autonomy vs. Duty of Care—the Old Age Psychiatrist's Dilemma

Adrian Treloar

Memorial Hospital, London, UK

The twentieth century has seen huge transitions in medical and legal practice based upon changes in the philosophy underpinning the way in which doctors relate to patients. At its lowest points, the Nazi programmes of extermination and forced sterilization in the USA, Sweden and elsewhere have demonstrated the capacity of doctors for abuse of their patients[1]. In the UK poor-quality procedures around consent, and scandals such as patients being charged by carers for their weekly bath and other "privileges", have shown just how easy it is for the vulnerable to be abused. Arising from this has been a philosophical, legal and medical trend towards self-determination and autonomy. Advance directives have been promoted as a solution to the loss of autonomy. They have, however, been shown to have limitations. Indeed, one study found that the entire health gain from cardiac rehabilitation programmes was neutralized because patients in the study signed advance directives[2].

Old age psychiatry must, if it is honest, admit that it views autonomy as a limited concept. The use of legal tools such as the UK Mental Health Act to detain mentally ill patients, along with the widespread housing of demented people behind locked doors, even without a formal detention order[3], shows that autonomy does not rule undisputed. There is also evidence that the practice of administering medication covertly within foodstuffs is widespread in the UK[4]. How can we justify such acts? In a landmark judgement, the UK Law Lords held that the mentally incapacitated could be detained and treated in their best interests because it was their illness that primarily removed their autonomy and not the fact of their detention[5]. Doctors and others may therefore treat the mentally incapacitated against their wishes when the patients themselves will clearly benefit from such treatment.

This shows that old age psychiatrists have an inescapable and awesome responsibility to balance the principles of autonomy and good clinical care when they are in opposition. This balancing act must be open to scrutiny and requires that good clinical care of the patient is the focus. The twentieth century was too heavily littered with examples of patients' needs coming second to the intentions of others for it to be otherwise. In essence, to be trustworthy, doctors can never intend harm.

Psychiatric Services in Long-term Care

Ira R. Katz[1,2], Kimberly S. Van Haitsma[3] and Joel E. Streim[1,2]

[1]*University of Pennsylvania,* [2]*Philadelphia VA Medical Center and* [3]*Philadelphia Geriatric Center, Philadelphia, PA, USA*

Older people require long-term care when they have care needs that go beyond what they and their families can provide. It can consist of subacute, step-down or convalescent care for individuals discharged from hospitals, rehabilitative services for those recovering from illness or injury, and hospice care for those with terminal illness, as well as life-long care for those with irreversible disability. Increasingly, the landscape of settings for long-term care is expanding to include home- and community-based programs. Even for those who require residential care, the options are expanding to include increasingly diverse forms of assisted living or personal care facilities, as well as nursing homes. Nevertheless, nursing homes remain the most important settings for long-term care, especially for those individuals who are oldest and most disabled. However, nursing homes are also evolving, with increasing numbers of patients admitted for short stays for subacute or rehabilitation care and a proliferation of special care units designed for patients with dementia.

According to recent government reports[1–4], there are approximately 1.6 million residents occupying 1.76 million beds in 16 840 American nursing homes. For persons who turned 65 in 1990, an estimated 43% will enter a nursing home at some time. Of this group, 55% will have a total lifetime use of at least 1 year, and 21% will have total lifetime use of 5 years or more. Although both the number of facilities and the number of beds increased almost 20% from the mid-1980s to the mid-1990s, they did not keep pace with the growth of the elderly population. The ratio of nursing home beds to the size of the population aged 75 years and over dropped 17% from 1987 to 1996—127–117 beds/1000 people. However, the occupancy rate declined from 92.3% in 1987 to 88.8% in 1996. Thus, the nursing home market is beginning to experience the combined effects of healthier aging and the availability of alternative approaches to long-term care.

US nursing homes are heterogeneous: 65.5% are for-profit vs. 27.9% non-profit, 6.6% are government-owned; 53.8% are owned by chains; and 13.6% are hospital-based. In 1997, 67.4% of nursing home costs were paid by Medicaid (approximately half of this paid by the federal government and half by the states), 9.4% by Medicare, and 23.3% from private funds or other payers. Federal payments account for the majority of expenditures for nursing home care and have been estimated in the late 1990s to be approximately $40 billion/year.

Among all US nursing home residents in 1996, the average age was 84.6; 9% were under 65, 12% 65–74, 30% 75–84 and 49% 85+; 71.6% of residents were women; 88.7% of residents were White, and 8.9% African-American; 13.9% required assistance with one or two activities of daily living tasks, and 83.3% with three or more; 88.2% required assistance with dressing, 96.5% with bathing, 59.7% with eating, 73.6% with transferring into or out of bed, 66.4% with mobility and 79.7% with toileting. Compared to comparable findings from a decade earlier, the average age of residents increased by 0.9 years; the proportion aged 85+ increased from 49% to 56% for women and from 29% to 33% for men. Disability of residents also increased and the proportion of those requiring assistance in three or more activities of daily living was 15% higher in 1996 than 1987.

The psychiatric needs of nursing home residents are thus those of a population characterized by extreme old age and high levels of disability. Accordingly, the delivery of psychiatric services in the nursing home must be informed by knowledge of the clinical psychiatry of this population. However, mental health providers must also be aware of other factors that shape the delivery of care. These include the potential for use of the nursing home environment as a therapeutic agent, either in Special Care Units for dementia or in other programs, and the extensive federal regulations that govern clinical services in US nursing homes.

CLINICAL PSYCHIATRY IN THE NURSING HOME

According to recent reports from the Nursing Home Component of the Medical Expenditure Panel Survey (MEPS), approximately 48% of US nursing home residents have a diagnosis of a dementia[1]. However, this figure probably underestimates the actual prevalence. Other MEPS data demonstrate that approximately 70% of residents have memory problems, 73% orientation problems, and 80% impairments in decision-making capacity. It also estimates that approximately 30% of residents have behavioral problems; 11.8% are verbally abusive, 9.1% are physically abusive, 14.5% are socially inappropriate, 12.5% are resistive to care, and 9.4% wander. In addition to this high prevalence of cognitive impairment, the MEPS reports that approximately 20% of residents have a diagnosis of a depressive disorder. Comparing these figures with comparable data from a decade earlier suggests that the number of residents with diagnoses of dementia or depression has increased. However, the number of individuals with schizophrenia has declined, especially among the younger residents[5]. Findings from this national representative sample confirm earlier research reports about the high prevalence of psychiatric disorders in nursing home residents[6]. In particular, they support the validity and generalizability of estimates from research in a single facility that demonstrated that 80% of residents have a psychiatric diagnosis. Findings from this earlier research provided insight into the nature of the disorders; 67% of residents had dementia, with most having Alzheimer's disease; approximately 40% of those with dementia had other psychiatric syndromes as complications (psychosis 13.5%, depression 6.3%, and delirium 7.3%); and 12.8% had other psychiatric disorders, most

commonly depression[7]. Among those with dementia, it was those with psychiatric complications who were most likely to exhibit behavioral problems.

The available findings suggest that, in spite of significant changes in American nursing homes over recent years, the high levels of psychiatric morbidity and the distribution of disorders has remained the same. There has, however, been significant progress in developing and validating treatments for psychiatric disorders in nursing homes. One particularly promising intervention for residents with dementia and behavioral problems combined augmented activities, guidelines for use of psychotropic medications, and educational rounds[8]. It was tested in a randomized clinical trial and found to be effective in reducing the prevalence of behavioral disorders and the use of both antipsychotic drugs and physical restraints. Another series of studies has shown that individualized consultations to staff nurses about the management of patients with dementia can reduce the use of physical restraints[9]. There has been little research on the effectiveness of specific psychotherapies for nursing home residents with depression. Although available findings are highly promising[10], research on individualized behavioral interventions for patients with behavioral and psychological symptoms of dementia have been limited to case series or small-scale controlled studies.

Psychotherapeutic medications are widely used in nursing homes. The US Health Care Financing Administration estimated that use of these agents increased during the 1990s from 21.7% in 1991 to 46.1% in 1997[3,4]. This reflected a 59.8% decrease in the use of antipsychotic medications from 33.7% to 16.1%, but a 97% increase in the use of antidepressants from 12.6% to 24.9%. These changes probably reflect a number of factors, including scientific developments, accumulating effects of professional education and specific federal regulations (as described below).

Two randomized clinical trials have demonstrated the efficacy of the atypical antipsychotic agent risperidone for the treatment of the psychotic and behavioral symptoms in residents with dementia[11,12]. The available findings suggest that it has both antipsychotic effects and independent effects on aggression or agitation. Longer-term follow-up studies suggest that it may cause less tardive dyskinesia than typical neuroleptics[13]. A randomized clinical trial of olanzepine vs. placebo has demonstrated similar efficacy[14] and additional findings on other atypical antipsychotic agents are expected in the near future. However, the controlled clinical trials on antipsychotic agents have evaluated only their acute effects, typically for periods of 6–12 weeks, and little is known about the effectiveness of antipsychotic drug treatment over longer periods of time. In fact, recent double-blind, placebo-controlled studies of neuroleptic discontinuation demonstrate that the majority of patients who have been receiving longer-term treatment with these agents can be withdrawn from them without ill-effects[15,16]. Two randomized clinical trials studies evaluated the efficacy of mood-stabilizing anticonvulsants for the treatment of agitation and aggression. One studied carbamazepine and found that it was effective for agitation, hostility and aggression but not for other symptoms, such as hallucinations or delusions[17]. Findings from staff reports demonstrated that treatment with active medication led to decreases in the nursing time required for patient care. Another recent study evaluated valproate vs. placebo and found evidence for efficacy[18].

There are now several acetylcholinesterase inhibitors approved for use in patients with mild to moderate Alzheimer's disease, and there have been questions about whether they are useful in treating nursing home residents with more advanced disease. One randomized clinical trial demonstrated that use of donepazil was associated with improvements in cognitive performance comparable to those observed in less impaired outpatients[19]. Although there have been suggestions that cholinesterase inhibitors may be useful in managing behavioral symptoms, this issue is unresolved at this time.

There have been two randomized clinical trials evaluating the effects of antidepressants in nursing home residents, both using the classical tricyclic nortriptyline. One of the studies was placebo-controlled[20]. Positive findings were used to confirm the validity of the diagnosis of major depression among nursing home residents in spite of potential confounds from medical, environmental and existential factors. Another finding from this study was that patients with major depression, low levels of serum albumin and high levels of self-care disability were less likely to respond to treatment; this led to the suggestion that patients with this clinical profile may benefit from early hospitalization and evaluation of the need for electroconvulsive therapy. The second study randomized patients to regular vs. low-dose nortriptyline and found significant plasma level response relationships in those patients who were cognitively intact, again confirming the validity of the diagnosis of depression[21]. However, the plasma level response relationship was significantly different in patients with dementia, suggesting that the depression of dementia may be a distinct disorder. There have been no randomized clinical trials of selective serotonin reuptake inhibitors (SSRIs) or related medications in nursing home residents, and available open-label studies have mixed results, especially with respect to the outcomes of treatment in nursing home residents with dementia[22–26]. In a related area, there is evidence from an older clinical trial that the stimulant medication methylphenidate may be useful in demented patients with symptoms of apathy and withdrawal[27].

The recent estimate that almost 25% of US nursing home residents are receiving an antidepressant medication reflects an extraordinary change in patterns for drug utilization, especially in light of findings indicating that a generation ago only 15% of residents with a known diagnosis of depression were receiving antidepressants[28]. Although significant components of current antidepressant usage may be for other putative indications, such as agitation, sleep or pain, it is important to note that reported utilization rates are comparable to estimates for the prevalence of depression. Research is needed to determine whether it is possible to demonstrate an impact of prescribing on the mental health of the population as a whole.

THE NURSING HOME AS A MENTAL HEALTH CARE ENVIRONMENT

In the past decade there has been a growing awareness of the importance of the psychosocial and mental health aspects of nursing home care and a number of conceptual models have been developed to focus on the person–environment interaction as the target for care practices. These have included "progressively lowered stress threshold"[29], "stimulation-retreat"[30], and "person-centered"[31–33] care. Other widely discussed concerns that reflect the increased awareness of the psychosocial aspects of nursing home care include quality of life[34], individualization of care[35], the importance of the patient's perspective[36,37], and autonomy[38,39].

Many of these concepts have been applied in the design and operation of special care units (SCUs) for residents with cognitive impairment. The popularity of these units has been phenomenal, with current estimates that 22% of nursing homes have designated SCUs for patients with dementia. Outcome studies evaluating special vs. traditional care have suggested positive effects in a variety of selected outcomes, such as the nature of the services provided, depression, family perception of quality of life and the rate of decline in mobility[40–43]. However, more rigorous randomized clinical trials have reported positive outcomes only in circumscribed areas, such as catastrophic reactions[44] and observed positive emotional responses[45].

While it is encouraging to find evidence that the outcomes of care in nursing homes may be modifiable, it is important to recognize that there are no effects that are consistent across studies. However, these mixed findings are not unexpected, given the tremendous variability in the definitions, structure and programs of SCUs as well as other methodological limitations, such as selection biases, attrition and measurement limitations. Therefore, many researchers have increasingly called for studies focused on the evaluation of specific interventions associated with improved comfort, health status and quality of life, in attempts to identify and evaluate the "active ingredients" of special care[37,46,47].

Many programs have been based upon modification of the physical environment to decrease behavioral difficulties and enhance positive quality of life in the nursing home. Promising programs that incorporate natural elements into the environment, include a bathing intervention that uses bird songs, pictures of nature and food during bathing to decrease agitated or aggressive behavior[48], and use of "white noise" machines emitting sounds of ocean waves or waterfalls[49]. The use of bright lights in the care environment has been shown to consolidate sleep and to reduce agitation, but only in those with disturbed sleep-wake cycles[50]. An intervention that decreased noise and light in the night-time environment did not, by itself, improve the quality of the residents' night-time sleep; however, when combined with a daytime program of increased physical activity, it did provide benefits[51,52].

Some programs have gained great popularity in the clinical community, but have not yet been evaluated in controlled studies. These include the "Eden Alternative", which attempts to increase biological diversity in the institutional setting by incorporating children, plants and animals into the day-to-day life of the nursing home[53], and horticultural interventions[54]. Another set of promising interventions are based upon spirituality or religiously-based programming[55,56]. Music therapies, in particular, have been studied more intensively and may be effective in increasing positive emotional and social engagement and decreasing problem behaviors[57].

Technological interventions have been used in the nursing home, either to provide enhanced surveillance to increase safety or to use modalities such as audio or videotapes as therapeutic tools. Only one of these therapeutic interventions has shown positive results after testing under controlled conditions—simulated presence therapy[58], in which residents with dementia are asked to listen to taped, simulated telephone conversations with family members, was superior to placebo in decreasing problem behaviors and increasing well-being.

Several studies have demonstrated efficacy in programs designed to promote functional independence in persons with dementia residing in the nursing home. One focused on altering "dependency support scripts" and found increased independent behavior on the part of residents[59]. Other studies have focused on evaluating programs designed to target specific functional capabilities. Several groups have found positive effects from programs that modify usual routines for morning care and dressing. One analyzed videotapes of dressing behaviors to develop care prescriptions, and found that these led to increased independence in dressing[60]. Another used a "skill elicitation" intervention and found that it significantly increased the amount of time participants were engaged in dressing and other ADLs, while simultaneously decreasing the frequency of disruptive behavior[61]. A third found that an "abilities-focused" program, teaching direct care staff to modify the moment-to-moment procedures used in morning care on the basis of knowledge of the residents' specific cognitive deficits, led to improvement in calm/functional behaviors, agitation and social functioning[62].

Other important factors affecting the psychosocial environment in nursing homes are those related to the caregiving staff. It is certified nursing assistants (CNAs) who serve as primary caregivers to a population characterized by ever-increasing levels of dementia, dependency and mental health disorders. There is no doubt that the increased demands on skills and time, together with the physically and emotionally demanding labor, require attention to selection, training, supervision, and a focus on the role of the CNA as a provider of psychosocial care. There are multiple sources of stress for these paraprofessionals, including individual self-related needs, off-the-job stressors, patient contact, and administrative and organizational factors. One study demonstrated that 57% of CNAs screen positive for clinically significant levels of distress[63]. However, the paraprofessional staff do not, as a rule, receive adequate support from the psychological and psychiatric community in addressing such issues as non-pharmacologic management techniques, assisting with family conflicts and coping with job-related stress[64].

Fortunately, there is evidence that training programs for CNAs can have positive outcomes for the CNAs, including increased interaction and sensitivity to resident cues, provision of more choice and praise, and increased behavioral management skills. Moreover, these can translate into improvements in residents' mood and functioning[65,66]. Another line of research has found that mental health outcomes can be affected by structural and organizational elements of nursing homes, such as chain status, size, staffing levels, turnover, staff selection, job assignments, job design and the adequacy of supplies; moreover, interventions modifying formal elements of staff management can have positive effects on staff behavior[67].

THE REGULATORY ENVIRONMENT IN US NURSING HOMES

Although nursing homes have historically been designed to care for patients with medical and surgical conditions, the vast majority of their residents have psychiatric disorders. The mismatch between resident needs and facility characteristics in US nursing homes has been associated with inadequate, inappropriate and even inhumane treatment[68]. During the 1980s, concerns expressed by advocacy and professional groups were reinforced by a report from the Institute of Medicine[69] documenting major problems in the quality of care provided in nursing homes. Specific issues included the undertreatment of depression and use of physical and chemical restraints to control behavioral symptoms in patients with dementia. Other concerns at that time were that elderly patients with chronic and severe psychiatric conditions were discharged from state hospitals and inappropriately placed in nursing homes at Medicaid expense, thereby denying them access to the active psychiatric treatment they needed, and shifting a substantial portion of the costs of their care from the states to the federal government.

Recognition of problems in the quality of care in US nursing homes, together with ongoing concerns about costs, prompted Congress to pass legislation, the Nursing Home Reform provisions of the Omnibus Budget Reconciliation Act (OBRA) of 1987[70], which has transformed nursing homes into one of the most highly regulated environments for healthcare delivery in the USA. To operationalize the laws enacted under OBRA '87, Congress directed the Health Care Financing Administration (HCFA), the agency that administers Medicare and Medicaid, to issue specific regulations that govern nearly all aspects of nursing home operations[71], and charged the states with the responsibility for conducting surveys to determine whether nursing facilities were in compliance. In response, HCFA developed a set of interpretive guidelines for state surveyors[72], which has been revised over the past 10 years to reflect changes in healthcare practice and policy. Mental health screening, evaluation, care

planning and treatment are addressed under sections of the regulations related to resident assessment, resident rights, facility practices and quality of care.

The OBRA regulations require preadmission screening and annual resident review (PASARR) to prevent inappropriate nursing home admissions for patients with severe psychiatric disorders, and to ensure that those with acute psychiatric conditions are not placed in nursing homes before receiving the benefits of acute psychiatric treatment[73]. However, patients who have a primary diagnosis of dementia are considered eligible for nursing home admission regardless of psychiatric complications or co-morbid conditions. After admission to a nursing facility, all patients are required to undergo periodic comprehensive assessments using the Minimum Data Set (MDS), a standardized instrument that includes several areas relevant to mental health: mood, cognition, communication, behavior patterns, activities, functional status, psychosocial well-being, oral/nutritional status, co-morbid disease, medications and other treatments[74]. Responses on the MDS that indicate deficits or changes in the patient's health status serve as triggers for resident assessment protocols (RAPs), which are second-stage assessment tools that furnish prompts to help nursing staff recognize signs and symptoms that are indicators of potentially significant clinical problems, algorithms to direct further evaluations, and guidelines for treatment planning. RAP problem areas related to mental disorders and behavioral health include delirium, cognitive loss/dementia, psychosocial well-being, mood state, behavior problems, psychotropic drug use and physical restraints. The regulations hold facilities responsible for ensuring that the MDS is completed on time and the RAPs are followed.

The OBRA regulations also contain provisions that affect psychiatric treatment in the nursing home, prohibiting the use of physical restraints or psychotropic drugs when they are "administered for purposes of discipline or convenience and not required to treat the resident's medical symptoms" or promote improved functioning[71]. There are specific regulations concerning antipsychotic drugs, designed to ensure that residents receive these agents only when "necessary to treat a specific condition as diagnosed and documented in the clinical record". The regulations also require periodic "gradual dose reductions and behavioral interventions, unless clinically contraindicated, in an effort to discontinue these drugs". Syndromes such as delirium and dementia, when accompanied by agitated or psychotic features, are listed among the accepted indications for the use of these agents. However, use of these medications must be supported by documentation that there are specific target symptoms associated with resident distress, functional impairment or danger to self or others.

Regulations related to quality of care further require that each resident's drug regimen be free from unnecessary drugs, defined as any drug used in excessive dose (including duplicate therapy); for excessive duration; without adequate monitoring; without adequate indications for its use; or in the presence of adverse consequences indicating the need for dose reduction or discontinuation[71]. The interpretive guidelines that accompany these regulations specifically limit the use of antipsychotic drugs, antianxiety agents and sedative–hypnotics, but not antidepressants[72]. For each of these medications, the guidelines provide a list of acceptable indications as well as specific agents that may not be used; daily dose limits which, if exceeded, require documentation that the benefits justify the risks; requirements for monitoring treatment and adverse effects; and time frames for attempting dose reductions and discontinuation. These guidelines were updated in 1999 to reflect new clinical knowledge and accepted practice and to include newly approved drugs.

Beginning in July, 1999, HCFA introduced quality indicators (QIs) derived from the MDS to enable surveyors to compare individual facilities to others in the same state[75]. There are 24 QIs within 11 different domains, including behavioral/emotional problems, cognitive patterns and psychotropic drug use. Behavioral/emotional patterns cover the prevalence of behavioral symptoms affecting others (e.g. verbally or physically abusive, socially inappropriate or disruptive behavior); prevalence of symptoms of depression; and prevalence of depression without antidepressant therapy. The cognitive pattern domain examines the incidence of cognitive impairment when consecutive MDS assessments reveal new onset of impairments in short-term memory or decision-making ability. The psychotropic drug use domain includes the prevalence of antipsychotic use for patients without psychotic conditions, the prevalence of antianxiety/hypnotic use, and the prevalence of hypnotic use more than twice in the previous 7 days. QIs that are indirectly related to mental disorders and their treatment include the use of nine or more different medications, and the prevalence of falls, weight loss, daily physical restraints, and little or no activity. Whenever a review in any of these areas results in a deficiency citation, a plan of correction must be developed and approved.

SUMMARY

In spite of significant changes in American nursing homes over the past 10–15 years, the high prevalence rates for dementia and depression remain as persistent problems. Fortunately, there have been major advances in knowledge about the outcomes of psychiatric care for nursing home residents. Chapters in textbooks from a decade ago may have been eloquent about the need for mental health services, but they had little to say about their outcomes. Now, it is possible to review evidence for benefits of specific interventions. In addition to pharmacological and behavioral treatments that are designed to be delivered to individual patients, other interventions are designed for delivery to nursing units or to residential care facilities as a whole. Promising interventions in this domain include augmented activities, modifications of the physical environment, use of technologies to augment interpersonal interventions, modifications in patterns for the delivery of basic nursing care, staff education, and changes in administrative structures. All of these must be delivered in the context of a complex regulatory environment. Thus, the delivery of psychiatric services in nursing homes must attend to the needs of the individual patients and to the context in which they receive care. To be successful, it requires partnerships between mental health professionals, direct care staff and the facilities' administration.

Care in Private Psychiatric Hospitals

K. G. Meador[1], M. M. Harkleroad[2] and W. M. Petrie[2]

[1]*Duke University, Durham, NC, and* [2]*Memory Disorders Center, Nashville, TN, USA*

Psychiatric care and treatment for mental disorders in the elderly in a private psychiatric setting is fundamentally a public health issue. The location of treatment and the clinical services available are shaped by public policy, financial incentives and the emergence of managed care. With the implementation of the Medicare Part A Hospital Insurance Trust Fund, most acute inpatient psychiatric care and treatment for the elderly in the 1970s and 1980s occurred in special geropsychiatric units in general medical units and private psychiatric hospitals. Data reflect the trend of the shift from public sector inpatient care to private and general medical hospital inpatient units. State and county organizations providing mental health care decreased 7.6%, while private hospitals increased 95.5% and general medical hospitals with inpatient mental health services increased 21.6%. The relative percentage of mental health expenditures for state and county hospitals decreased from 48.5% in 1975 to 23.6% in 1994 for total mental health expenditures; while the percentage of expenditures for private psychiatric hospitals increased from 7.1% to 19.5% during that same time period. Outpatient and community-based programs, including partial hospital programs, increased as a relative percentage of total mental health expenditures from 1.8% in 1975 to 26.8% in 1994[1]. In addition to addressing concerns inherent to providing quality medical care, any discussion focused on the care of older persons must include content regarding the logistical and ethical dimensions of financial and familial responsibilities. In the context of an increasingly aged population, Henderson[2] challenges us with a public health agenda of: (a) developing "bold and innovative means for assisting families to care for a relative with dementia"; (b) improving the "contributions of general practice to the care of mental disorders in the elderly"; and (c) investigating the social environment of the mentally ill elderly and promoting more adaptive alternatives when feasible. These challenges are particularly pertinent in the private psychiatric facility, where the "financial disincentives and shortages of trained personnel"[3] common to the discipline of geropsychiatry are frequently amplified.

There are several factors that necessitate the private psychiatric community becoming more aggressive and innovative in the care of older persons, despite the substantial constraints and disincentives. The first is the void left by the inadequacies in the community mental health center and the shift from treatment in state and county hospital programs for this population[4]. Second, the overall demand for inpatient psychiatric treatment for the elderly has continued to grow as the number of elderly, especially those over 80, has grown dramatically[5]. A third factor leading to an increased demand for private psychiatric care is that internists and primary care physicians are frequently not trained in the behavioral management of geriatric patients, and there is a growing subspecialty of geriatric psychiatry which is generating paradigms for diagnosis and treatment of older persons with neuropsychiatric and behavioral disorders.

The World Health Organization has identified acute inpatient psychiatric care as an important component in the continuum of care for the elderly[6]. Although the USA and the American Psychiatric Association have not published specific practice guidelines for geriatric inpatient treatment, there are generally accepted principles of quality care and treatment of elderly individuals in inpatient settings. These principles of care include: preadmission screening and linkages with community providers of care; comprehensive assessment and care planning; multidisciplinary staff with specialized experience and interest in the elderly; ongoing staff training and education; therapeutic programming and care approaches sensitive to the needs of an aging population; environmental and physical design of program; individual, group and family therapy; discharge and aftercare planning. With the emergence of managed care and financial incentives for community care, there has been a lack of coordination and integration of mental health services, especially for the elderly with severe mood disorders, psychosis, and dementing illnesses with complicating psychiatric and behavioral disorders. These forces combine to magnify significant gaps in treatment for the most frail and psychiatrically needy elderly who need comprehensive psychiatric and medical treatment, most appropriately provided in an acute inpatient geropsychiatric treatment program. Keill[7] proposes that it is "still possible within the system and with proper incentives to provide an accessible, comprehensive network". He emphasizes that within this network there must be a continuity of care, which is defined by Bachrach[8] as "a process involving the orderly, uninterrupted movement of patients among the diverse elements of the service delivery system". In the context of these challenges and stipulations, we present an example of a geropsychiatry service in a private hospital through which such issues can be discussed.

DESCRIPTION OF PROGRAM

The Parthenon Pavilion at Centennial Medical Center in Nashville, Tennessee, is a 162 bed private proprietary psychiatric hospital that has developed a cost-effective model program for the delivery of acute inpatient geropsychiatric services. The hospital currently operates two 12 bed Alzheimer's disease and related disorders–memory disorders units and a 16 bed general

geropsychiatry unit, which together function as a regional referral center for the treatment of the elderly with complex and concurrent psychiatric and medical problems. Parthenon Pavilion's geriatrics program opened in 1985 and the original memory disorders unit was developed in 1987. This program provides a structure for supporting continuity of care by organizing clinical services and concentrating resources around the diverse and specialized needs of patients with severe psychiatric disorders, often complicated by behavioral difficulties and/or serious medical problems. The hospital also includes a geriatric partial hospitalization program which adds another dimension to the continuum of psychiatric care for senior adults.

Clinical Process

The geriatrics program has developed a philosophy of treatment and a clinical services model that places an emphasis on interdisciplinary care, so as to provide psychiatric and medical management of treatable symptoms in order to reduce distress, disability and complications in the older patient. A second major tenet of the program's treatment philosophy is that the family and professional caregiver systems are helped by providing: (a) accurate diagnosis and education around the nature of disease processes in the context of the unique manifestations of a disease in a given individual; and (b) supportive assistance and practical guidance tailored to the care and management issues of a given patient and caregiver system. This clinical services model also places a high priority on providing consultative and clinical liaison services to families, agencies, nursing homes and residential facilities, to assure continuity of care and maintenance of the clinical goals established during hospitalization for patients after they are discharged from the program.

The importance of family involvement in such a program cannot be overstated. Hardwig[9] challenges the ethically simplistic notions of patient autonomy frequently espoused when he points out the integral role of the family in making medical decisions. This is especially relevant when working with older persons, due to the prevalence of cognitive impairment found in this group. When a patient becomes demented, family members must frequently assume decision making in medical situations. This may violate family taboos as well as established patterns of family interaction, which may require renegotiation. Family conferences, as a means for mediating the moral process of medical decision-making and planning for ongoing care, are an integral aspect of the clinical services offered by the Geriatric Program, and result in a consistently high level of family satisfaction.

Administrative and Team Function

The administrative structure of this program includes: the clinical director, who is a psychiatrist specializing in geropsychiatry; a program director who is a Master's-trained social worker; a nurse manager with experience in geriatric nursing; and access to a clinical nurse specialist with a Master's degree in psychiatric nursing. The clinical director provides leadership in program planning, program evaluation and quality assurance, while also being available to provide consultation to other attending psychiatrists as needed. The program director coordinates the day-to-day operation of the program and works closely with the clinical director and nurse manager in implementing the above-designated functions.

Each patient has an attending psychiatrist, who directs the treatment, meets with families in diagnostic feedback conferences, participates in clinical liaison activities with nursing homes and other placement facilities and develops an aftercare plan, along with other disciplines represented on the staff[10]. The program is supported by a number of psychiatrists with added qualifications in geriatric psychiatry and considerable experience in the treatment of such patients. Although many private psychiatric facilities have limited professional staff with particular expertise in geriatrics, such persons are increasingly available, due to an increasing number of specialized training programs. The program is joined by a group of board-certified internists, who have special interest and expertise in evaluating and treating acute and chronic medical problems in the elderly. Upon admission, the internist conducts a comprehensive review of systems and physical examination on each patient. Throughout the hospitalization, the internist provides follow-up of existing or developing medical problems and, when necessary, participates in family conferences and team staffing. Medical subspecialists, such as neurologists and cardiologists, are consulted when clinically indicated and their availability is fostered by the fact that the hospital/program is part of a regional tertiary care medical center which also provides access to available technology, brain imaging, laboratory services and specialized neuropsychological testing as medically indicated.

Nursing care is delivered through a primary nursing system. Nurses are recruited who have strong medical/surgical background along with geropsychiatric interests[11]. Meeting these staffing demands remains challenging, particularly in an era when most hospitals are experiencing professional nursing shortages. Supportive nursing administration within the program and the promotion of educational opportunities have fostered a reduced staff turnover rate well below the 20% annual rate experienced nationally[12]. The program director and the nurse manager are involved in pre-admission screening and clinical liaison activities, along with providing inpatient clinical services to family and professional caregivers. The social workers coordinate discharge planning and aftercare follow-up, which is a vital linkage in maintaining continuity of care. Activity therapists conduct functional assessments and design appropriate activities for the units within the program, according to the level of function of the patients. They can provide feedback to families and professional caregivers regarding functional abilities and deficits, making recommendations for modifications in the patient's environment and activities to support remaining abilities. Staff education is conducted through a variety of means, including weekly teaching rounds conducted by the clinical director, monthly interdisciplinary staff education meetings, and special teaching modules designed by the clinical nurse specialist.

Physical and Environmental Features

The physical design of the geriatric program provides for separate units divided by a nursing station. Two are for patients with dementia and memory disorders; the other for the general geriatric population. Prior to the development of the specialty units, demented patients were integrated with non-demented patients and separate therapeutic activities and groups were planned for each population[13]. However, it ultimately was determined that separating the program into specialty units, serving cognitively impaired patients with Alzheimers's disease and related disorders and a general geropsychiatric unit provided the optimal arrangement both clinically and administratively. The memory disorders units are designed for security and have unit doors that can be locked. Such a unit is specifically designed and adapted for the particular needs of sensory and cognitively impaired persons. There is an emphasis on music, videotapes and appropriate sensory stimulation without overload. The general geropsychiatry unit and the memory disorders units are pod-shaped, with a day room outside the bedrooms, and have activity

rooms that can be used for special activities as needed. The care environments are designed to be adaptive in nature and focus upon remaining rather than lost abilities.

Financial Considerations

A necessity in the private psychiatric hospital is to operate in a cost-effective manner, so that the program does not have a significantly negative financial impact on the hospital. One means of achieving this goal has been to establish a program-based preadmission screening and consultative service to assure that each person admitted to the program meets Medicare intensity and severity criteria for a psychiatric admission. The pre-admission service also screens for persons primarily needing medical treatment or long-term care, and focuses on orientating the family and referral sources to the goals and limitations of inpatient psychiatric treatment. Consultative and crisis management assistance is provided when hospital treatment is either inappropriate or not immediately available.

Another means of maintaining cost-effective utilization of resources is to avoid inappropriately extended stays by assuring that discharge planning begins with the preadmission process and is an integral aspect of ongoing treatment. Length of patient stay is monitored through a case review-orientated quality assurance program, coordinated by the program director working in cooperation with the clinical director. Regular review of the length of stay and systematic documentation of reasons for continued hospitalization not only enhances the quality of care but also provides a peer-reviewed justification for continued stay when reviewed by regulatory agencies. A major challenge during the past decade has been the shift to Medicare Managed Care, an HMO, for cost containment and utilization. A goal of such programs is to achieve more cost-effective care and treatment and to prevent unnecessary hospitalization. However, aggressive cost containment can negatively affect access and quality of care for the elderly with severe mental disorders and dementia, complicated by co-morbid medical conditions. This effort has resulted in undertreatment and limited access to inpatient care. In addition, with psychiatric care ‘‘carved out’’ of medical benefits and financial incentives to limit care, the distinction between medical and psychiatric coverage in demented patients may have significant financial impact on third-party payers.

Summary

In summary, the key elements of the program used in the model emphasize: (a) preadmission assessment and screening in the context of consultative services; (b) treatment by an interdisciplinary team, which includes an attending psychiatrist, internist, primary nurse, social worker, activities therapist and other ancillary staff, each with a commitment to the particular needs of the older person; (c) individualized educational programs for families and professional caregivers to augment existing clinical services; (d) individualized behavioral approaches that incorporate written behavioral management plans as an adjunct or substitute for psychopharmacological approaches; (e) discharge and aftercare planning services, family conferences and post-hospitalization follow-up with families and institutional caregivers; (f) environmental and physical design; and (g) cost-effective inpatient treatment. Approaches for assuring continuity of care for individual patients with complicated behavioral and psychiatric symptoms have included written behavioral prescriptions for families and caregivers, demonstrations of appropriate caregiving techniques during hospitalization, and videotape demonstrations designed to serve as training tools for nursing home staff members. In 1999, Parthenon Pavilion provided leadership and financing for a new initiative to focus on improved mental health care for older adults. The initiative represents an innovative approach to clinical collaboration among select organizations providing mental health services to the elderly. The clinical Senior Links mental health consortium included representatives from home health, the local mental health association and Alzheimer’s association, a community mental center and senior center providing community-based mental health services, staff of Parthenon Pavilion, and geriatric partial hospital programs located in the community. This program serves as a potentially innovative approach to improve the delivery of mental health services for senior adults and provides a forum for focusing on improved access, assessment and treatment, aftercare coordination and education for the consortium members and the community.

CHALLENGES FOR THE FUTURE

The primary challenges facing private psychiatric hospitals serving the elderly include: (a) monitoring and modifying admission criteria as Medicare intensity and severity criteria continue to become more restrictive and prospective payment is implemented; (b) developing intervention strategies with family caregivers to avoid inappropriately extended stays for non-clinical reasons; (c) maintaining quality care in the context of financial disincentives, especially magnified by increased enrollment in Medicare managed care plans, and regulatory policies which impact negatively on hospitals serving geriatric patients with severe psychiatric illnesses frequently complicated by behavioral and medical problems; (d) maintaining quality staff in all disciplines, especially with the growing nursing shortages and shrinking revenues; (e) developing consultative and outreach services to respond to the growing trend for nursing homes to serve increased numbers of residents with mental disorders and severe dementia with psychiatric and behavioral disorders.

We face these challenges in a cultural and federal regulatory environment that is ambivalent at best in its support of Medicare. Medicare accounted for only 9% of the federal budget in the USA in 1989, but sustained 36% of all budgeting cutbacks. Of even greater consequence for the elderly with mental disorders is the fact that Medicare spends only 3% of its budget on mental health care[14]. The claims are made that ‘‘key business values, including attention to a guiding mission statement, the needs of consumers, accountability and marketing, have a positive impact on the quality of milieu treatment’’[15], but these assertions are put forth in a consumer-market paradigm and the pitfalls of this approach have not been adequately assessed. Tischler[16] points out the lack of systematic studies that include qualitative intermediate or long-term outcomes of mental health care. Studies examining utilization review outcomes have included only service utilization and expenditures. The program model presented here is committed to perpetual quality improvement, but clinical quality and reimbursement issues are inextricably linked in the private setting and future excellence may be jeopardized if current trends continue.

Quality of Care and Quality of Life in Institutions for the Aged

M. Powell Lawton
Philadelphia Geriatric Center, PA, USA

Although the form and function of the institution for older people changed considerably over the second half of the twentieth century in the USA, UK and other countries, the central task endures—providing protective care for older people unable to care independently for themselves. At the beginning of this period there were still people in the system whose lack of independence was primarily financial. Physical ill-health and, later and into the present, mental and cognitive ill-health became the main reason for entry into an institution.

The details of how such care was delivered differed in major ways across countries, to the point where knowledgeable comparisons were possible only for highly specialized experts who had the time to become familiar with more than one system. The present chapter is written when such differences are still evident. It is thus necessary at the outset to acknowledge that any attempted generalization about institutions for the aged must be interpreted in the light of differing cross-national social and cultural traditions. Nonetheless, this chapter will assert that there are characteristics common across localities that are universally accepted as indicators of quality of care and quality of life in institutions for older people (sometimes referred to as "nursing homes", as in the USA).

After establishing the importance of the quality concept, this chapter will review issues in maintaining quality in this type of residential case. Some of the recent literature will be reviewed, followed by the presentation of a model for defining quality of care and quality of life now under development by Rosalie Kane, Robert Kane and the author.

WHY BE CONCERNED ABOUT QUALITY IN NURSING HOMES?

Quality has been an issue among US nursing homes from the beginning of such institutions. Governmental monitoring of quality has been a threat to for-profit entities because their profits might be threatened by external quality-monitoring efforts. Poor quality may also be found among governmentally sponsored and non-profit homes. Suffice it to say that there has always been a major gap between accepted standards and the actuality of care, sometimes to a shockingly unacceptable degree, in the USA.

Governmental regulation, although resisted by many elements of the nursing home network, has been the major device used to enhance the quality of nursing home care in the USA. The system now in place requires each state to hire and train professionals ("surveyors") to spend time at least every second year on site with staff, residents and archival records to assess each institution on a series of written standards.

The procedure for monitoring nursing home quality required by the US government is instructive in defining current standards. There are 185 such regulations, which are organized into 15 categories: resident rights; admission/discharge rights; resident behavior and institutional practices; quality of life; resident assessment; quality of care; nursing services; dietary services; physician services; rehabilitation services; dental services; pharmacy services; infection control; physical environment; and administration[1]. Classification problems are immediately apparent. All categories are aspects of quality of care, and many may also reflect quality of life. Both of these subcategories are defined for monitoring purposes in a much more limited way than seems appropriate to this author. In 1997 the 10 most prevalent deficiencies in US nursing homes were: food sanitation; resident assessment; care plans; accidents; pressure sores; quality of care; restraint use; housekeeping quality; dignity; and accident prevention[2].

Citation for deficiencies may result in fines, temporary suspension of reimbursement for care or, at worst, removal of a license and closing of the institution. Suspension of reimbursement or license rarely occurs; in fact, the problems of finding care for residents in the offending institution are viewed as more stressful than continued low-grade care. Regulation is quite different, of course, in the UK. For instance, until recently it was only privately-administered facilities that were subjected to outside regulation, on the theory that local authorities were, by definition, assuring adequate quality by the nature of their direct responsibility for care[3]. This separation has changed, however. It seems likely that the phenomena of diversification of sponsorship (especially into the for-profit sector) and the need for local authorities to lean more heavily on professionals for quality controls than on local monitoring will make the two countries' systems become more similar in the future.

DEFINING QUALITY OF CARE

The classic system view of the health-care institution denotes the structural, given characteristics as input, care and treatment as process, and the resultant effect on the patient as output[4]. It has been noted frequently that output is difficult to identify when the institution constitutes the last residence and the final outcome is death. In addition, research over the past couple of decades has

demonstrated the dynamic character of the structure of institutions. Administrative, care-delivery and physical environmental changes in fashion, including remodeling and simple space-use changes designed to encourage desired behaviors, attest to the ability of most institutional elements to be shaped toward higher-quality care[5].

Thus the literature of quality of care has been characterized either by value-based assertions that particular processes were intrinsically associated with higher quality of care, or were statistically correlated with overall quality as assessed by experts. The Institute of Medicine (IOM) report on nursing home quality called for making direct assessments of performance outcomes in terms of clearly undesirable states, such as death rate, infection rate, decubitus rate, or malnutrition[6]. More recently, other indicators reported on the required periodic assessment contained in the Minimum Data Set of the US nursing home system (MDS) have included accidents, questionable medication use, restraint use, infections and other obviously undesirable outcomes[7,8].

DEFINING QUALITY OF LIFE

Clearly, poor-quality care will lower overall quality of life. A distinction between quality of care and quality of life is useful to make, however. In a rough sense, quality of life must include features of everyday life that enhance enjoyment and sense of hope or purpose above the average level. An individual's quality of life is a subjective assessment made by that person alone. Quality of life of an environment, such as a nursing home, is represented by institutional attributes that have a statistical probability of leading to higher individually perceived quality of life for its occupants. There is thus a dual perspective on quality of life, the individual–subjective and the environmental–objective[9].

If quality of life is to be monitored, both perspectives must be assessed. Ideally, positive features of residential care would be identified by their association with positive subjective responses by a majority of the consumers of such care. The importance of the consumer was recognized in the regulations that followed passage of the Nursing Home Reform section of 1987 legislation[10]. Nursing homes are required to solicit opinions on the quality of care and quality of life experienced by residents.

In practice, however, it is not possible to demonstrate a direct parallel between nursing home resident perspectives and features that represent quality in the institution. Until the state of the art of measuring both consumer evaluation and environmental attributes is further advanced, it is necessary to make many assumptions about what constitutes quality, based on the available literature. Thus, the assessment system must encompass a large array of both personal and environmental features.

A Conceptual Basis for the Search for Quality

Kane, Kane and Lawton[11] have found it convenient to organize quality into 11 domains: security; functional competence; comfort; dignity; autonomy; privacy; meaningful activity; social relationships; enjoyment; individuality; and spiritual well-being. These domains represent universal individual needs, whose satisfaction may be enhanced or blocked by the environment in which the person pursues the gratification of needs. In overview, an approach to assessment evaluates the extent to which residents' needs are fulfilled and the extent to which environmental features relevant to these needs are present. Although the actual design of the measures is still in process, their components may be viewed as a model that could be useful for later investigators.

Resident Needs

Many modes of consumer assessment have recently become available[12,13]. Our own approach queries residents systematically about their evaluation of how well the residential environment fits each need. All such direct approaches require ordinary comprehension of questions and the willingness to respond frankly. Because many people in residential care are cognitively impaired and others may be loath to express critical comments, other complementary or parallel sources of information must be sought.

Resident Needs as Perceived by Others

Caregiving staff and family members are an obvious source of information on some domains. Such characteristics as functional health, cognitive performance, participation in activities or depression may be rated by an outsider. Some intrinsically subjective domains are less amenable to these types of judgments, e.g. the degree to which dignity is experienced in nursing home life. An outsider may assess a resident's ongoing affect states but clearly is limited in access to the resident's actual happiness, sadness or other feeling states[14].

Direct Observation

On the other hand, systematic observation by research staff or quality-control staff may reveal very concrete instances of behavior relevant to quality of care and quality of life. An observer may be trained to be less susceptible to bias than the resident in terms of denying socially unacceptable behavior, and is capable of being instructed in the subtle indicators of quality that may be exhibited in settings such as morning care, mealtimes, activities or unprogrammed time. Examples from earlier research include systematic observation of the "behavior stream" or the non-verbal indicators of emotional state[14,15]. It is also possible to train experts in more global aspects of direct observation that focus on concepts rather than small behavioral acts. The Professional Environmental Assessment Protocol (PEAP)[16], for example, requires an environmentally trained professional to spend about an hour in a care area, after which global ratings are made on the environment's ability to foster orientation, safety and security, privacy, stimulation quality, regulation of stimulation, functional competence, personal control, and continuity of self[17]. One important way in which direct observation adds to the quality attainment process is that it allows for the input of expertise in judgments of quality. Not all goal-relevant information is evident to the consumer. Some of what is learned from observation is thus complementary to the resident's perspective.

Integrating the perspectives of residents, significant others and objectively-viewed phenomena is not a straightforward process. Although most experts would wish to give primacy to the views of residents themselves, around 20–40% are cognitively unable to express evaluations and preferences that might guide the enhancement of quality[18]. It might be argued that the most-capable 60% should be able to articulate a consumers' view that would also fit the cognitively impaired. We must recognize, however, that major impairments in cognitive and self-care ability may also translate into needs quite different from those who are intact. The perspectives of significant others and value-judgments based on observable behavior clearly add something to knowledge about quality. Yet we cannot automatically substitute them for the absent judgments of those who are too impaired to be questioned. At best, putting together the three perspectives is at present more an artistic endeavor than a scientific one. How one accounts for biases in perspectives or for the differential weighting

of the several types of input into measuring quality are tasks for the future.

The Economic Perspective

This chapter cannot do justice to the economic ramifications of quality of care and quality of life. In general, increased quality comes at a cost. In the case of both the profit-seeking institution and the governmental or non-profit institution, there are obvious constraints on the extent to which higher quality can be financed. This observation helps identify another distinction between quality of care and quality of life. Quality of care, being a life-and-health issue, is capable of being defined in terms of minimally acceptable threshold levels. These levels can in turn be defined reasonably clearly and used as the basis for licensing or potential decertification.

CONCLUSION

It is a different issue whether what has been defined as quality of life can be audited and used legally to improve the quality of nursing homes. Surveyors could conceivably become equipped to diagnose quality-of-life deficiencies and cite them to the point of removal of licensure. This appears problematic because quality of life has so many subjective aspects. Surveyors would no doubt be reluctant to make such citations and political pressure from owners would minimize the legal clout of such citations. One possible outcome is that the present survey process will continue to be used to correct the most egregious lapses in minimum quality of care. Beyond the merely adequate quality of care attained by correcting basic deficiencies, improvement in quality of life up through the positive to excellent ranges may be a matter better controlled by the marketplace than by legal enforcement. Quality-of-life audits could lead toward intrafacility self-assessment, staff training and growth, articulating possible avenues for improvement on which administration and staff could work proactively. The greatest weakness of the market-place hypothesis, however, is that the present market is responsible primarily to the upper income range of client families. If market-driven improvement in quality of life is to occur, we should have to see greater equalization of opportunity and increasing competition for the patronage of government-subsidized residents as well as those who pay in full for their care. Despite such difficulties, we should leave room for the possibility that improved quality of life in nursing homes may emerge better with indigenous rather than legal motivation. In the UK, there is some hope that the cultural and ethical norms may support the general public and governmental view that quality of care and quality of life are both basic rights of all citizens. This motivation might over time become more effective than either legal regulation or market competition[19].

Liaison with Medical and Surgical Teams

Sheila A. Mann

Clacton and District Hospital, Clacton-on-Sea, UK

In one of the early textbooks of geriatric medicine, Agate[1] wrote, "As a sign of acute physical illness in old age, mental change is more significant than a rise in temperature or pulse rate . . .". Not only is delirium (acute organic brain syndrome) more frequently found in old age than in earlier life, but the incidence of dementia rises sharply and affective disorders, particularly depression, remain common. Thus, someone presenting with medical or surgical problems may well have coincidental, as well as causal or resultant, psychiatric symptoms. It is hard, therefore, for physicians and surgeons to ignore the psychiatric problems of their patients.

PREVALENCE OF PSYCHIATRIC DISORDER IN NON-PSYCHIATRIC INPATIENTS

A number of investigators have surveyed psychiatric disorder present in patients in non-psychiatric beds. Lipowski[2] estimated that psychiatric disorder or distress of significant degree was present in 30% of the patients he studied. Bergmann and Eastham[3] published a series of 100 elderly patients admitted to an acute medical unit in the UK, whom they screened for psychiatric disorder. They found that 7% had a diagnosis of dementia, 16% delirium and 19% functional illness. Mezey and Kellett[4] summarized a series of UK studies and found prevalence of 5–51%.

Nowhere are such numbers of patients referred for a psychiatric opinion. Other studies have investigated consultation rates.

CONSULTATION RATES

Wallen[5] and her co-workers looked at consultation rates in short-term general hospitals in the USA, using a national sample of 327 hospitals. This was retrospective and adequate information was not recorded in 25% of the hospitals. Patients admitted specifically for a psychiatric illness were excluded. Less than 1% of those admitted were referred for psychiatric opinion. The highest rates were in hospitals attached to medical schools, those in urban areas and those in the north-eastern USA. Not surprisingly, these characteristics were highly correlated with each other.

Wallen and co-workers found that, in general, female patients and younger patients were more likely to be referred. Those referred were sicker, i.e. had been given more "medical" diagnoses, and had more complex problems. They therefore tended to use more resources. Ethnic origin was not a significant variable, but payment system was. Patients on Medicaid (government financed medical care for low-income persons) were more likely to be referred than those admitted under private insurance schemes.

In this, as in many earlier studies, all ages were considered together; in subsequent work, consultation rates for elderly patients were compared with those for younger patients. For instance, Popkin *et al.*[6] compared a series of 266 psychiatric consultations to patients aged 60+ with consultations to a younger group. They found that the consultation rate for patients under 60 was 2.85% and for those aged 60+ 1.99%, a highly significant difference. In no specialty service did the rate for those aged 60+ exceed that for younger patients. The diagnoses given by psychiatrists differed between older and younger patient groups: 46% of the older group were diagnosed as having organic mental disorder compared with 14% of the younger inpatients. The psychiatrists also recommended more psychotropic medication for the older patients, which could be explained by the high percentage of organic diagnoses, and more diagnostic tests, which could not. The psychiatrists assessing the elderly patients were not described as specialists in geriatric psychiatry.

In the UK, consultation rates were also studied. At Guy's Hospital, Anstee[7] looked at the pattern of referrals in 1968–1969—10 years after Fleminger and Mallett[8] had done so. He found that the referral rate had doubled from 0.7% to 1.4%. Of the 254 patients referred, 49 were elderly; 35 had been referred from medical and 13 from surgical wards. Also at Guy's Hospital, Poynton[9] compared referrals from August 1982 to November 1983, when there was no specialist psychogeriatric consultation service, with those from December 1983 to January 1985, when such a service had been introduced. The rate of referral rose from 0.64% to 1.40%, there being a greater rise in male referrals (0.34% to 0.96%) than in females (0.97% to 1.17%). In both periods, depression was the commonest single reason for referral. Anderson[10] reported a similar rise in referral rate following the setting up of a specialist consultation service in Liverpool. The rate rose from 0.7% to 1.96%; proportionately more referrals were for depression in the second period (p. 142).

WHY SUCH LOW REFERRAL RATES?

Goldberg[11] suggests that medical and surgical patients are referred for psychiatric opinion either because some cue alerts their doctor

Principles and Practice of Geriatric Psychiatry, 2nd edn. Edited by J. R. M. Copeland, M. T. Abou-Saleh and D. G. Blazer

that there is a psychiatric problem or because the symptoms cannot be accounted for by known organic disease. He has suggested five reasons for non-detection:

1. Many patients do not provide cues, although they will describe their problem if asked.
2. Patients often mention depression or anxiety at the beginning of the interview, together with somatic symptoms, but only the latter are selected for further questioning.
3. Medical histories are often taken in open wards, where lack of privacy does not encourage patients to mention psychiatric problems.
4. A known organic cause does not exclude a psychiatric disorder.
5. Even when a psychiatric disorder is suspected, many clinicians are not confident of their ability to make a psychiatric assessment.

Other reasons for non-detection/non-referral that have been postulated include the following:

1. Attitudes of physician and of patient/patients' relatives. Physicians may still cherish misconceptions that depression and cognitive impairment are an inevitable accompaniment of ageing or that psychiatric disorder is not amenable to treatment. Fauman[12] found that 19% of surgeons and 9% of physicians believed that psychiatric illness was incurable. Elderly patients and their relatives may have a greater fear of public exposure and stigma than younger ones, although this may be changing.
2. Alternatively, some physicians may have an increased tolerance of cognitive and behavioural disturbance in their elderly patients.
3. Cognitive impairment, or symptoms such as paranoia, may make it hard for patients to relate their symptoms.
4. Some doctors feel that organic mental disorder is not a psychiatric problem.
5. Psychogeriatric services may be inaccessible, either geographically or personally, i.e. if too much pressure on the psychogeriatrician delays liaison visits.
6. There may be fear that a psychiatric referral will lead to an increased length of stay, either for further investigation or for treatment.
7. Physicians may wish to treat their patients' psychiatric problems themselves. They appear particularly likely to wish to treat depression, anxiety, psychosomatic disorders and organic brain disease, and most unlikely to wish to treat suicide attempts or psychoses[12].

The commonest reasons for referral are generally for advice on management, including drugs, or assessment of cognitive state. Other reasons include delayed recovery, advice on the psychiatric side effects of drugs, help in the selection of patients for other procedures, "disposal" problems or because of a previous psychiatric history. Covert reasons may emerge, e.g. a history of conflict, either between members of the medical team or between team and patient, especially when the patient declines to follow medical advice. The psychiatrist may then be expected to act as mediator.

There is no doubt, also, that referral rates may depend on local or personal factors. In one hospital, a high referral rate was thought to be due to the siting of the psychiatrist's office next to the medical ward, resulting in many verbal referrals.

Benbow[13], reviewing the old age psychiatry service in the centre of a large conurbation, found that most referrals from hospital doctors (58%) came from physicians in geriatric medicine, the remainder from other physicians and surgeons. These referrals accounted for 35% of the department's work load.

OUTCOME

What is the effect of referral to the psychiatry of old age service? In terms of immediate outcomes, the most frequent consequences appear to be suggestions for further investigation, advice concerning psychotropic medication, social services, counselling or other brief psychotherapeutic intervention or behavioural approaches by ward staff. Few patients are judged to need transfer to a psychiatric bed—6.6%[14]; 9%[15].

Querido[16] found that there was a significant increase in the chance of recovery for patients looked after by a team consisting of a physician, a social worker and a psychiatrist, assessing all aspects of their care, compared with those treated in a conventional way. He found that predictions based on team assessments were more accurate than clinical forecasts based on the patients' physical illness.

Others have shown that psychiatric disorder present during an inpatient stay is associated with subsequent increased mortality rates; e.g. in open heart surgery[17] or from myocardial infarction[18,19]. Treatment might be expected to have a positive effect on the mortality rate. It has also been shown that psychiatric intervention can lessen length of stay[20,21].

Hawton[22], following up a cohort, examined during admission by Maguire *et al.*[23] after discharge, found that the presence of a psychiatric disorder during the initial admission was associated with higher subsequent mortality. He found that increased mortality rate was associated with age (not surprisingly) and the presence of psychiatric disorder. Excess mortality was not just due to more deaths in hospital or shortly after discharge, neither could it be explained by a higher percentage of patients with organic mental disorder; the mortality rate was also higher in patients with affective disorder.

Cooper[24] screened 626 patients aged 65–80 in an urban West German hospital and followed them up 1 year later. He found that the outcome—whether measured in terms of mortality, dependency or admission to continuing institutional care—was worse for those with organic mental disorder, 42% of whom had died at follow-up; 18% of those with functional illness, and the same percentage of those with "normal" mental states, had died. Functional illness appeared to correlate with increased dependency on others (42% needed help, as against 29% of "normals").

Feldman *et al.*[25] obtained similar findings: 49% of patients aged 70+ with organic mental disorder died within a year of assessment, compared with 20% of those without cognitive impairment.

Johnston *et al.*[26], in a prevalence study of psychiatric disorder in patients aged 65+ in non-psychiatric beds in a district general hospital, found that patients with significant psychiatric disorder had a greater length of stay. This appeared to be largely due to problems in placement.

Although some work has been done on the effects of intervention, less attention has been paid to financial aspects, either due to psychiatric intervention, or saved by it. This is becoming of vital importance to everyone in health care. Levitan and Kornfeld[27] studied outcome in a group of 24 patients undergoing surgery for fractured femur, where there was extensive liaison, and compared it with outcome in 26 patients treated in the same surroundings but without involvement of a psychogeriatrician. Mean length of stay for the first group was 30 days and for the control group 42 days, a significant difference. Twice as many

liaison patients returned home, as opposed to discharge to institutional care.

A SPECIALIST PSYCHOGERIATRIC LIAISON SERVICE?

Evidence has been cited to show that there is much undetected psychiatric disorder in patients occupying non-psychiatric beds, that there is a higher mortality rate in patients with such disorder, and that psychiatric intervention can reduce length of stay. Even though it would be wrong to assume, as some psychiatrists do, that all patients with emotional disorder require specialist assessment, it is probable that a good deal of suffering on the part of patients and their relatives and carers could be avoided by early detection and treatment. There is therefore a case to be made for a liaison service to elderly, as well as to younger, patients: "Coordination of medical care with any psychosocial care is likely to result in a better outcome and more effective use of medical services"[25].

Two models of service have been described: a "consultation" service and a "liaison" service. In a "consultation" service, the psychiatrist will only see patients specifically referred. Because of pressure of work, many of these assessments take place outside normal working hours and therefore without direct contact with the referrer. As a rule, further investigation and management will be recommended and will be carried out by the referring team. There is frequently no further contact with the psychiatrist unless problems occur—"please get in touch with me again if necessary...".

In a liaison service, a member of the psychiatric team joins the medical or surgical team usually on a weekly basis, e.g. on a ward round. He/she will take an active role in the further management of the patient. In practice, geriatric medical services most frequently have an attached liaison psychiatrist and many services offer a mixed consultation/liaison model.

Swanwick *et al.*[28] compared the two models. They found no major differences in reason for referral, broad diagnostic category or in suggested intervention and follow-up. They did find that in the liaison model there was a higher percentage of accurate diagnoses made by referring physicians.

Concern has often been expressed that the introduction of such a service would lead to too great an increase in referrals for the capacity of the old age psychiatry unit. Swanwick *et al.*[28] found no evidence for an increased referral rate—in fact, in the liaison model there were fewer referrals relative to the number of beds.

In other services, an increased referral rate has been described. Scott *et al.*[29], after setting up a liaison service with a senior psychiatric trainee (a specialist registrar) attending geriatric medicine ward rounds, found a 100% increase in the referral rate initially. Referrals from medical teams increased, while those from surgical teams remained the same, at a small percentage. This, however, was counteracted by the benefits achieved. Like Swanwick, she found an increased accuracy in diagnosis, 28% of patients referred having a diagnosis of affective disorder as against 12% before the service was introduced.

Studies have generally found that, with an increased knowledge of psychiatric disorders and the potential beneficial effects of treatment, there are fewer inappropriate referrals and physicians treat more such disorders themselves. Scott[29] and Baheerathan and Shah[30], who also studied the introduction of a liaison service, found that the benefits of charge in referral pattern more than offset the cost of the liaison psychiatrist.

Most of the consultation/liaison work described has been carried out by psychiatrists. Collinson and Benbo[31] describe a successful liaison service using an experienced psychiatric nurse. Others, for example Camus *et al.*[32], advocate the benefits of a full multiprofessional psychiatric team working within the general hospital with patients in non-psychiatric beds.

Why should this not be part of an overall liaison service, which might have organizational advantages? What can specialist psychogeriatricians offer? This has been answered by Popkin *et al.*[6]; they will have special knowledge and awareness with respect to the evaluation of physical illnesses that give rise to psychiatric symptoms; they are practised in differentiating organic mental disorder from mood disorders; they have extensive knowledge of psychotropic medication and of the consequences of altered pharmacokinetics in elderly people; and they are well equipped to evaluate and address psychosocial factors, the family and social support. Some of the aims of a psychogeriatric liaison service are listed in Table 134.1.

What will be the problems of providing such a service? They are likely to include:

- The identification of need.
- Accessibility of interested psychogeriatricians.
- Acceptability to patients, relatives, physicians/surgeons and members of their teams.
- Fear of increased length of stay for diagnosis and/or treatment.
- The cost—and who should pay.

With respect to identification of need, much can be done in educational programmes with all (not only medical) staff. In fact, most psychiatric disorder will be suggested by an adequate medical and social history and examination, as is taught in undergraduate curricula. Often the importance of this is not appreciated, and time and other factors do not encourage it. Other staff—nurses, occupational therapists, physiotherapists and social workers—are well able to identify and describe psychiatric problems if they are taught what to look for. They are also able to initiate plans for discharge at an early stage, e.g. with orthopaedic patients, rather than waiting until surgical rehabilitation is complete. Psychiatric staff need to learn the needs of their colleagues on the general wards and how to assist them; in particular, the fear and distress that mental illness and behavioural disturbance arouse in those unaccustomed to them. It is thus imperative that psychogeriatricians be involved in planning in-service training.

The use of screening tests has been shown to increase detection rates. The subject has been discussed extensively in recent papers[26,33,34]. Geriatricians have found the abbreviated Mental Test Score[35] useful for cognitive impairment. The Mini-Mental State Examination[36] and the Clifton Assessment Procedures for the Elderly[37] have some advantages, the latter being rather long but more inclusive, the former quicker and therefore more acceptable. It is more difficult to single out tests for functional illness: brief versions of the General Health Questionnaire[38,39] or the Geriatric Depression Scale[40] have been shown to be useful.

Table 134.1 Aims of a psychogeriatric liaison service

- To increase awareness of the prevalence and benefits of treating psychiatric disorders in elderly people
- To stress availability of psychiatric advice
- To provide a well-published referral system
- To offer a prompt response
- To offer a clear, practical assessment and recommendations with explanation, and transfer if needed
- To adopt a helpful attitude to behavioural disturbance
- To provide follow-up as inpatient and after discharge, if necessary
- To run an acceptable educational programme
- To undertake an evaluation of service

The Brief Assessment Schedule[41] has been used to screen for both organic and functional disorder.

The majority of psychogeriatricians in the UK are aware of the importance of liaison; their accessibility varies. The organization of the service depends on local factors; many liaison services are based on linking a psychiatric team with one or more specialist firms. This has worked for much of adult psychiatry and has benefited both teams. It may conflict with the more usual pattern in psychiatry of old age services, where the team is responsible for residents of a defined catchment area and "follows" them throughout their care.

Those in other specialties need to know of the psychogeriatric liaison service. Notices in ward information packs and inclusion in induction courses for new staff are essential. Often the provision of a special referral sheet, such as that in Figure 134.1, helps both to remind and to focus on the information needed by the psychiatrist. There must be a means of telephone referral—preferably one number, with the psychiatric department sorting out the details of who should deal with the referral. As there must be an emergency service available out of hours, and this is usually provided by the duty psychiatrist, he, too, needs instruction.

Acceptability is usually best achieved by the results of an effective service. For instance, Bergmann and Eastham[3] stated that, with respect to affective disorder, when liaison work took place staff attitudes on medical wards changed, including "... a new enthusiasm and willingness to look for affective disorders in other patients and to try to obtain treatment for them whenever possible".

Similarly, fear concerning length of stay and cost can best be assuaged by explanation and discussion, and finally resolved in the light of successful practical experience.

Education and the Liaison Psychogeriatrician

D. N. Anderson
Mossley Hill Hospital, Liverpool, UK

The elderly are under-represented among referrals to psychiatry from general hospital wards in relation to younger patients and bed occupancy. Less than 3% of general elderly admissions are seen by a psychiatrist and only 20–25% of all liaison contacts are with older people, even though they occupy 40–50% of general hospital beds and 30–50% might be expected to have or develop a psychiatric problem[1]. This represents 3000–5000 cases/10 000 admissions and even if more were referred, only a fraction could realistically be seen by a psychogeriatrician[2].

The frequency of mental disorder in acute elderly medical admission populations is approximately twice that of the community[3,4]. Depression, dementia and delirium are the common syndromes. Psychiatric problems are much more common on medical and orthopaedic than general surgical wards[5–7]. The frequency of organic brain syndromes increases with age[8] but there is less evidence that depression is age related[9].

The identification of mental disorder by general clinicians is poor[10], particularly the detection of depression[11] and delirium[12,13]. Clinicians appear to detect the syndrome of dementia more reliably than cognitive symptoms[14] but with depression it is symptoms that are more often recognized than the syndrome[15]. The possible adverse effects of a co-morbid psychiatric disorder upon the outcome of a medical admission makes the recognition and treatment of these disorders important to both patient and clinical service[6,16,17].

A priority for the psychogeriatric consultation–liaison service has to be education (acting as it does at the interface between psychiatry and general departments) that encourages good practice and alters attitudes to mental illness in old age. With such morbidity it is essential to improve the ability of general staff to detect and prescribe appropriate treatment for the majority of simple disorders, while recognizing those cases that need the specialist psychiatric service[18]. Currently, the treatment of mental disorder by general staff, particularly for depression, appears poor[19].

There is indirect evidence that specialist consultation–liaison psychiatry for the elderly does influence the behaviour of general clinical staff toward psychiatric problems. The introduction of a consultation–liaison service is certainly associated with increased rate of referral[1,20–23]. This increase is most marked for depression[1,23], perhaps the most neglected and inappropriately managed condition, but close liaison produces a general improvement in the quality of referrals[23].

Research in the old age liaison field is in its infancy and has concentrated on quantifying levels of morbidity, examining referral rates and exposing clinicians' difficulties in recognizing psychiatric disorders. Preliminary work suggests that psychiatric involvement with older patients can have positive effects on outcome[24] but this may not be targeted at the most appropriate cases[18]. If the management of mental disorder in this context is to improve, then general services will need education. The process of education is complex and multifaceted and a new research direction would involve a closer examination of the enabling role of specialist consultation–liaison, identifying approaches and style of service with the greatest educational impact and the most effective methods of disseminating knowledge and expertise.

It is the management of non-referred cases that will ultimately prove the measure of success. As the ageing population grows, this research is timely and these important areas of study need to be explored.

Rehabilitation

Rob Jones

Queen's Medical Centre, Nottingham, UK

Rehabilitation of the older person with psychiatric disorder means restoring and maintaining the highest possible level of psychological, physical and social function despite the disabling effects of illness. More broadly, it also means preventing unnecessary handicap associated with illness, preventing unnecessary handicap secondary to maladaptive responses to illness, and combating the deadening effects of low expectations of older people amongst patients, families and society in general. Managing chronic disease and disability is the greatest challenge to modern medicine. Within this, the rehabilitation of many older people with psychiatric disorder looms large—although, of course, many old people with psychiatric disorders respond well to "curative" therapy and require little rehabilitation.

In fact, rehabilitation is a fundamental and inseparable part of old age psychiatry. Perhaps for this reason, as with rehabilitation in geriatric medicine[1], little has been written about the topic specifically. Some particular techniques, such as psychological approaches with the cognitively impaired, have been well described[2,3] but little evaluated[4], and evaluative research is much needed here.

SPECIAL PROBLEMS WITH PSYCHIATRIC DISORDER IN THE ELDERLY

"Old age" may span 30 years or more, posing quite different rehabilitation problems; but the most major concern is with the old-old. In this group, multiple disability is prominent, with the complicating danger of polypharmacy, and physical and mental ill-health interact in complex ways. With this frail population, disentangling the respective influences of ageing, previous personality and current ill-health can be exacting. Two-thirds of the UK's disabled population are older people and the true extent of handicap due to psychiatric disorder is probably still not established.

With depression, especially, there may be restriction of physical activity, threatening physical capacity and health. Depression associated with stroke disorder[5] or with Parkinson's disease[6] particularly illustrates both the connection between physical and psychiatric problems and the importance of physiotherapy in psychiatric rehabilitation.

Physical factors are frequently of great importance in dementia. A quiescent individual may become delirious and disturbed at night through heart failure, obstructive airways disease or even the uncomfortable effects of severe constipation. Settling such problems may transform the reality of care for a carer and seeking out such therapeutic opportunities is an important part of rehabilitation. Similarly, in dementia, physiotherapy to promote and maintain the best possible physical capacity is a key element. Advice and practical aid to carers, such as with lifting and handling the physically disabled demented person, can be crucial.

A judicious mixture of the "therapeutic" (curative) and the "prosthetic" (supportive) approaches[7,8] is very necessary in old age psychiatry. Whilst much functional psychiatric disorder and delirium can be "cured", and this must be the aim, most older people with dementia need some degree of supportive care at some stage. The poor financial and housing state of many older people, together with the lack of children or spouses to help as carers for many of the old-old, are further complicating factors. Maximizing "participation" despite psychiatric disorder needs to be a major goal, maintaining as far as possible a role in the family, social contact, a range of activities and a minimization of loss of autonomy or institutionalization. This requires an approach that embraces psychiatric, medical, rehabilitation, nursing and social perspectives. Seeking active prevention of disability/reduced participation as a consequence of psychiatric disorder is a vital part of rehabilitation.

SPECIAL PRINCIPLES IN REHABILITATION OF THE OLDER PERSON WITH PSYCHIATRIC DISORDER

Table 136.1 summarizes the principles. The first principle is to make the home the focus of attention. That is where problems have arisen and where they will need to be overcome. Planning for rehabilitation should begin at the earliest moment; an initial assessment at home by a senior psychiatrist, or other experienced team member, is invaluable—even if "home" is an institution in the community. Home is also where the carers, and often any social services support staff involved, may readily be found. This contrasts with standard medical rehabilitation, where often no such opportunity exists.

Table 136.1 Principles of rehabilitation for the older person with psychiatric disorder

Focus on the home
Ensure comprehensive assessment
Encourage normal function
Treat the treatable
Analyse disabilities and chart progress
Clarify team goal with patient and carers early
Clarify team goal with support workers early
Teach what can be relearnt
Adapt the adaptable
Coordinate support and follow-up
Promote flexibility and ingenuity
Promote realistic optimism

Frequently further assessment by, say, an occupational therapist, physiotherapist or another specialist team member may be necessary—and this can perhaps also be arranged at home. But avoiding disruptive admission should not be at the cost of meeting assessment needs. The day hospital and its team is often useful to complete such assessments.

Poor function or morbidity should never be accepted as immutable and still less as normal. Assessment should aim at a thorough understanding of social, physical and psychological function, as well as the previous pattern of personality and lifestyle. From this, diagnoses and specific treatment for the treatable should follow. But also analysis should show the extent of disability, how it is mediated and how it may be overcome. Problems should be clearly recorded, with proposed solutions and with regular review of progress[9,10]. From the earliest moment, independent function and improvement should be sensitively encouraged, especially with hospitalized patients.

As early as possible, the agreed goal of rehabilitative efforts needs to be clarified with the patient, with the relatives/carers, with the whole rehabilitation team and with any support workers needed in the community. Education, guidance and a rehabilitative "demonstration" may well be necessary to resolve conflicting views on the prospects for progress. Carers may need therapy or rehabilitation in their own right. Almost always the support of carers is essential, although some stoutly independent patients manage well without this.

A prognosis-based plan is useful. This means assessing: what are the problems and what are their causes? Prognostication will follow: will these get better or worse? To what degree? Over how long a period? From this a plan can flow consistent with what seem the most major likely developments of a problematic nature, over a foreseeable timescale and taking account of what is most remediable.

Sometimes, disability strongly distorts the previously stable power and dominance pattern in the family[11] so that, for instance, a forceful mother becomes dependent on a passive daughter. Relationships are always important and such phenomena can strongly influence outcome. They need to be understood and often complex ambivalence worked through[12]. Such factors are frequently important when carers seem reluctant to resume caring[13] and need to be carefully teased out when juggling with the various elements of risk and risk minimization in supporting a vulnerable person at home[14]. The patient's "crutch is not made of wood but of some other person's tolerance or patience"[15].

An agreed balance should be sought between the needs of carers and the patient's right and desire for continued comparative independence despite significant disability—bearing in mind the team's prime responsibility to the patient. In effect, carers should be "recruited" as rehabilitation therapists' "aides". But often they will need practical help and advice on rehabilitation techniques and, always, the reassurance of the services' continuing availability for support and sensitive expert response. Similar considerations apply with any support staff necessary to help the patient at home—principally social services staff in the UK. Their early involvement and integration into the assessment and rehabilitation process can be logistically difficult but generally is most effective. Good teamwork is of the essence. Clarity and consistency within the multidisciplinary specialist team are essential. Nurses and therapists, for instance, must communicate well, each complementing and enhancing the other's approach. Specialist and general practitioner must be in accord. The specialist team must carry the confidence of those who will work with the patient outside hospital. Table 136.2 lists many of the team members and resources requiring coordination for rehabilitation—inevitably there is great overlap[7]. Clear goals should be set, in accord with patient and carers, and clearly understood by all[16,17]. This is much easier said than done with the vulnerable frail elderly person; but vitally important is good communication.

Patients are taught what they can learn or relearn but often only modification of domestic equipment, provision of aids or modifications of the home will overcome their disability. More often still, problems are only overcome through support services—home-delivered meals or a home help/community care assistant—coming into the home. Ingenuity and diplomacy may be needed with an old person reluctant to accept such necessary support. The great majority of support is provided by relatives/carers and supporting the supporters is the main task. This may require day hospital therapy, day care or respite admissions. Maintaining confidence in the care service is vital.

At some stage with hospital patients, except in the most grossly deteriorated person, a home assessment is advisable with an occupational therapist or physiotherapist, or both, and perhaps with other team members. Hospital-based staff can be too pessimistic and, allowed to function in his/her familiar environment, even a significantly demented patient can sometimes perform surprisingly well. Often serial home assessments are helpful with increasing challenge, leading to overnight stays. Also, initial failure to manage satisfactorily should not preclude the possibility of later improvement with further therapy or support.

Above all, rehabilitation with older people requires flexibility allied to a realistic but constructively optimistic approach. Innovation and ingenuity are frequently necessary. The complex interaction between physical, social and psychological factors in older patients is further complicated by the likelihood that

Table 136.2 People and facilities to aid rehabilitation of the older person with psychiatric disorder

	Specialist psychiatric team	Social services and local authority services	Primary care team
People	Psychiatrists Ready access to geriatricians Hospital nurses Community psychiatric nurses Physiotherapist Occupational therapist (OT) Clinical psychologist Social worker (Speech therapist—sometimes) (Dietician—sometimes) Carers' groups	Social workers Domiciliary services manager Home help/community care assistants Meals on Wheels Community OT Support to voluntary sector Sitter services Carers' groups	General practitioners Practice nurse District nurse Health visitor
Facilities	Assessment ward Nursing home Day hospital Outpatients Long-stay and respite care facilities	Luncheon club (often voluntary) Day centres (often voluntary) Long-stay and short-stay residential care Housing adaptation Sheltered housing	Health centre

circumstances, perhaps especially physical health, may change dramatically; this demands a flexible response. The solution, carefully constructed and successful on one day, may need major change on the next as the situation radically alters. For this reason, rehabilitation with older people is rarely completely finished and ''maintenance'' measures are often necessary. Careful planning of continuing care, follow-up and continuing availability as problems arise are essential features. The strength and determination of patients, relatives and support staff are considerably bolstered by the knowledge that this approach is backing them up.

REHABILITATION AND LONG-STAY CARE

Many patients, predominantly demented individuals, will require long-term care but rehabilitation must remain a strong theme. Such deteriorating multiply-disabled demented patients require 24 h care. They often exhibit difficult and disturbed behaviour and need heavy physical care. Providing the best quality of life, given often quite limited resources, is the aim and a major strategy is preventing unnecessary dependency and promoting the maximum retention of function. With descriptions[18] of the care of such patients in various settings, a frequent theme has been the availability of skilled and expert staff from the multidisciplinary team to help maintain good function. Evaluation of such long-term care programmes has proved complex and difficult[19,20].

There has been concern in the UK that such disabled patients will increasingly be excluded from hospital care for funding reasons, in favour of health authority contracted private nursing home care or simply standard care in private nursing homes[20–22]. In the USA (and many other countries), much long-term care of older people has long been provided in the private sector. But in the USA the Omnibus Budget Reconciliation Act (OBRA Act)[23] requires nursing homes to ascertain and meet any needs for therapy and treatment. In the UK the fear is that the drive in the best hospital care to provide a good quality of life may be replaced in private nursing homes by a desire for a quiet life; passivity and dependency (possibly resulting from unnecessary tranquillizing medication[24–26]) could be more acceptable than the patient's exercise of individuality, movement and self-expression.

Reports of high levels of depression in homes for older people[27–30] emphasize the worry about effective rehabilitation and care for older people with chronic psychiatric disorder. Any institution providing shelter is at risk of providing a relatively impoverished environment[15] and undue restriction of independence.

Bennett[15] called unnecessary social inactivity and dependence ''the psychiatric equivalent of contractures''. Hospitals (and social services) have provided much good practice. Accounts of good long-stay care for demented people emphasize the invaluable input of occupational therapy, physiotherapy and person-centred approaches[30,31]. Sensibly ensuring activity in a structured day and enriching the environment with, for example, music therapy, art therapy, drama therapy[32] or reminiscence therapy[33] are important wherever the setting.

Community psychiatric nurse (CPN) support (indeed, availability of all the specialist team to give support) to such homes can be feasible and helpful. But concern remains about how to monitor effectively and maintain standards in private long-stay care[20]. Ultimately, good care here depends on the commitment of sufficient appropriately trained staff to help disabled old people experience to the full their remaining scope for independence and capacity for joy.

ATTITUDES

Adverse feelings about older people have been noted by many[34]. Geriatricians have commented on unhelpful attitudes in health professionals of all kinds, including GPs[13]. Modern medical education is inculcating a better knowledge base for tomorrow's doctors and also better attitudes[35]. The educational potential of psychogeriatric services, not least exploiting the educational opportunity afforded by rehabilitation (and other concerns) with the most disabled, has been described[36]. Not only medical students[37], but all varieties of medical and other professional staff concerned with older people with mental health problems, and also carers and lay audiences, benefit from this educational effort. Public education especially is vital in engendering constructive attitudes in society, on which ultimately will depend all efforts towards care in the community and the political will to provide decent services.

Anaesthetics and Mental State

David Gwyn Seymour
University of Aberdeen, UK

The anaesthetist uses many drugs that directly or indirectly affect mental status and, as is discussed below, age-related changes in drug handling tend to increase the risk of adverse cognitive effects. The multiplicity of drugs used in modern anaesthesia also increase the risk of drug interactions, and at the same time make it more difficult to decide the cause of any adverse effect that occurs. For instance, a typical general anaesthetic might involve premedication drugs, intravenous induction agents, gases and volatile agents, competitive neuromuscular blockers, drugs to reverse the neuromuscular blockade, opiate and non-opiate analgesics (which may be given pre-, intra- or postoperatively) and major and minor tranquillizers.

It might be thought that a "regional" anaesthetic (such as a local, spinal or epidural anaesthetic), where the patient maintains consciousness, would be free from central nervous system effects. However, premedication is often given prior to a regional anaesthetic and sedatives and analgesics may be administered during and following the operation. All of these may have a prolonged effect on mental status. Regional anaesthesia might also influence postoperative outcome, for good or ill, by affecting the ability to mount a "stress" response.

Apart from the expected pharmacological effects of anaesthetic agents on mental status, there are also unwanted reactions to be considered, such as the increased tendency of anticholinergic drugs to precipitate acute delirium in older patients. Secondary drug effects may also be important, such as the disturbance of sleep pattern by opiates, which has been hypothesized as a cause of late postoperative hypoxaemia. Many of these individual effects are discussed below.

It should also be appreciated that an acute or chronic change in cognitive state which follows an anaesthetic may have nothing to do with that anaesthetic. Acute delirium can be precipitated by a variety of "stresses", including acute illness and non-anaesthetic drugs, and also by withdrawal from drugs, such as alcohol and tranquillizers, which were being taken prior to surgery[1,2]. Neurological damage following operation may result from hypotension or cardiac arrhythmias, which had nothing to do with the anaesthetic, hypocarbia may reduce cerebral blood flow, and the patient who appears demented for the first time following emergency surgery may have been dementing quietly and unobserved for many months before.

In an attempt to bring some structure to the above complexity, the following discussion will be divided into three parts: first, age-related changes in drug handling which are of particular importance to the anaesthetist; second, major direct and indirect mechanisms by which anaesthetic agents might affect mental function; and third, short-term and long-term studies of psychometric testing before and after anaesthesia (including the effects of clinical risk factors and type of anaesthetic, and the findings of the ongoing ISPOCD studies). It should be recognized, however, that the list is not exhaustive. For example, an operation under anaesthesia, like any other major life event, may precipitate anxiety and other changes in mental status[3].

Cognitive changes that occur after open heart surgery have also been well studied in the literature. However, in this group of patients, the cerebral effects of the cardiac bypass procedure add another layer of complexity to the analysis of the postoperative outcome, and they have not been further discussed in the present brief account, although part of the recent comprehensive review into postoperative cognitive dysfunction by Dodds and Allison[4] deals with this subject.

AGE CHANGES IN DRUG HANDLING THAT ARE OF PARTICULAR RELEVANCE TO THE ANAESTHETIST

As a broad generalization, Dodson[5] has subdivided anaesthetic drugs into two classes:

1. Drugs to which the elderly patient tends to demonstrate *increased sensitivity*. This class embraces most of the drugs that affect the central nervous system, including sedatives and analgesics. Such drugs usually have a more profound and long-lasting effect in the elderly. There may also be an increased incidence of side-effects of drugs in old age, such as muscle rigidity following fentanyl, and delirium following anticholinergic agents.
2. Drugs that act on the autonomic nervous system, where the elderly patient tends to demonstrate *decreased sensitivity* at receptor sites. Thus, the effects of autonomic blockade by anticholinergic drugs or β-blockers may be less dramatic, as may be the effects of vagal and sympathetic stimulants.

While the above classification is a useful conceptual framework, dosage regimens in individual elderly patients need to take into account individual differences in drug susceptibility, age-associated illness and physiological status. In most cases, however, the anaesthetist will need to give smaller doses of drugs to elderly patients[5,6].

In a more recent review, Dodds[7] has described anaesthesia as "applied clinical pharmacology with enough patho-physiology to confuse the picture". He lists nine key points, three of which are of direct relevance to mental function, and six of which are of potential relevance:

1. The minimum alveolar concentration (MAC) is that concentration of an anaesthetic gas which suppresses movement in

response to a surgical stimulus in 50% of subjects. MACs tend to fall with age.
2. Because of reduced neuronal density and a reduced metabolic rate, the elderly may be more sensitive to a given amount of anaesthetic drug. In elderly patients with a delayed circulation time, there is an added potential for overdosage when intravenous agents are given too fast, because a delayed response may be mistaken for a lack of therapeutic effect, so that when the drug eventually reaches the brain, too much drug has been given. Smaller doses, slower rates of infusion or repeated small boluses are recommended in the elderly.
3. The elderly appear to have an increased sensitivity to opiates.
4. Where there is pre-existing ischaemic heart disease, the patient may be vulnerable to the cardiac depressant effects of some anaesthetics. There is also a theoretical risk that some anaesthetic agents can "steal" blood from ischaemic myocardium by increasing vasodilation in normal vessels.
5. With increasing age there is a tendency to increased shunting in the lungs and decreased cardiac output. These pathophysiological changes have complex effects on the uptake of volatile gases, as a low cardiac output favours rapid uptake, while a decreased lung function produces the opposite effect. Such effects are less with the more insoluble gases.
6. Hepatic metabolism and/or clearance of drugs tends to be affected by age, although there is considerable interindividual variability. Insoluble anaesthetic agents which require no hepatic metabolism should be safer than soluble agents. Some anaesthetics, such as halothane, are also potentially hepatotoxic.
7. Renal clearance of drugs tends to fall with age in some, but not all older people. Some anaesthetics, such as sevoflurane, are potentially nephrotoxic.
8. Neuromuscular blocking agents can be classified into depolarizing types and non-depolarizing types. The non-depolarizing agents are usually favoured in old age.
9. Non-steroidal anti-inflammatory agents are increasingly being used for analgesia in younger patients, but may present increased hazards in the elderly because of nephrotoxicity, fluid retention and tendency to gastric irritation.

MECHANISMS BY WHICH INDIVIDUAL ANAESTHETICS MIGHT AFFECT MENTAL FUNCTION

A fuller discussion of this topic can be found in the review of Dodds and Allison[4], but major potential mechanisms are as follows:

Direct Cerebral Effects

Trace amounts of general anaesthetic agents can have effects on alertness and concentration after patients recover consciousness. Experiments involving young volunteers have also documented the effects of subanaesthetic doses of drugs on mental function, behaviour and motor skills[8,9], and have also studied the effects of prolonged general anaesthesia in the absence of surgery[10]. None of these studies involved old subjects, but it would be expected that the central effects of anaesthetics would become more marked with age.

Hypoxaemia

In recent years, pulse oximeters have provided a convenient, non-invasive means of monitoring postoperative hypoxaemia[11]. The new technology produced some unpleasant surprises: many elderly patients who appear to be stable and well-perfused experience profound and prolonged episodes of nocturnal hypoxaemia several days after surgery. Such episodes might explain some of the "unexpected" episodes of confusion, cardiac abnormality and sudden death that can occur up to a week following operation. However, as discussed in the review of Dodds and Allison[4], some researchers are not convinced that hypoxaemia is a major cause of temporary or permanent postoperative cerebral dysfunction (POCD), and the ISPOCD1 Study (see below) failed to find a correlation between hypoxaemia and postoperative cognitive status, even though it set out with the hypothesis that such a relationship existed.

The mechanisms by which anaesthetic agents, particularly opiates, might cause postoperative hypoxaemia are reviewed by Jones and his colleagues[11]. It appears that postoperative hypoxaemia is caused by the interaction of two major factors. The first of these factors is a gas exchange abnormality induced during anaesthesia, which tends to be most marked in the first few postoperative hours but which may persist longer. The second factor is episodic obstructive sleep apnoea, which may occur several nights after anaesthesia. The episodes of obstructive breathing seem to be precipitated by the *return* of rapid eye movement (REM) sleep, which had been abolished for a few days by drugs, particularly opiates, given around the time of operation, and by the stress of operation itself. This late hypoxaemia, once recognized, can be alleviated by giving oxygen, but in high risk patients a week of oxygen administration may be required.

Anticholinergics

As has already been explained, anticholinergic drugs tend to be less effective in blocking cholinergic function in old age. Much more important, however, are the direct central effects of anticholinergic drugs (such as atropine) that can cross the blood–brain barrier. In some cases excessive drowsiness results, while in others hallucinations and delirium occur, and some authors refer to a "central anticholinergic syndrome". A number of drugs that are not primarily anticholinergic agents also have anticholinergic properties, including phenothiazines, pethidine, thiobarbitone, flurazepam and tricyclic antidepressants. Two decades ago, in a small group of open heart surgery patients aged 29–75, Tune *et al.*[10] reported that the presence and severity of postoperative delirium was correlated with the level of anticholinergic drug activity in the blood. More recently, O'Keeffe and Chonchubhair[13] have reviewed the potential contribution of anticholinergic drugs to postoperative delirium, and have considered their importance relative to other pharmacological and non-pharmacological mechanisms.

While the evidence is not absolutely conclusive, it would seem prudent to minimize anticholinergic use in older surgical patients. One way to achieve this would be to avoid anticholinergics in premedication regimens, or perhaps to avoid premedication altogether. If an anticholinergic drug is thought essential, then glycopyrrolate, which does not cross the blood–brain barrier, would appear to have advantages over atropine[14].

COGNITIVE TESTING IN YOUNG AND OLD PATIENTS BEFORE AND AFTER SURGERY

Postoperative Delirium

Before considering the more subtle cognitive effects that can occur postoperatively, the syndrome of acute postoperative *delirium* will be discussed. The causes of postoperative delirium,

as in delirium in other settings, include acute illness, drugs and drug withdrawal[1,2,13,15] but the incidence tends to rise with age. Estimates of the incidence of postoperative delirium in the over-65s range between 7% and 50%, depending on the definitions used and the clinical circumstances[2,13,15]. The incidence tends to rise with age, the urgency of surgery, the use of sedative and anticholinergic drugs and the degree of preoperative mental impairment. Factors (such as sepsis) that favour the development of delirium in a non-surgical situation[12] may also be of relevance postoperatively.

Recent advances in the study of postoperative delirium have included attempts to standardize definitions[13] and a large study in the USA by Marcantonio *et al.*[15], which attempted to develop a clinical prediction rule in 1341 patients aged 50+ having major non-cardiac surgery. The latter authors found that seven preoperative factors (age over 70, alcohol abuse, poor cognitive status, poor functional status, serum electrolyte/glucose disturbances, thoracic surgery and aneurysm surgery) had an independent relationship with postoperative delirium. However, the effect of intraoperative events, including anaesthesia, was not studied, as the aim was to produce a preoperative rule.

O'Keeffe and Chonchubhair[13] have concluded that, in at least 90% of cases of delirium following general surgery, it is postoperative medical or surgical complications that are to blame, which implies that the appearance of delirium should lead to a diligent search for underlying physical medical problems. The increased incidence of postoperative delirium with age is likely to be due to causes such as these, rather than effects arising from age-related differences in handling anaesthesia[16].

Postoperative Changes in Psychometric Tests in Older People

Delirium is an important postoperative syndrome, but more worrying is the possibility that *dementia* could occur for the first time as the direct result of *routine* surgery and/or anaesthesia (as opposed to the mental changes that might arise from an intraoperative catastrophe, such as cardiac arrest). In 1955, Bedford[17] published a much-quoted retrospective study in which he sought to trace those patients in the Oxfordshire area who had "never been the same again" after an elective or emergency anaesthetic. Over a 5 year period he was able to identify 18 cases where there was reasonable evidence that dementia had appeared for the first time after surgery and anaesthesia. In interpreting this data, it is important to realize that a detailed assessment of preoperative mental function was not available, and that even in cases where dementia was reported immediately following surgery, it did not necessarily imply that anaesthetic drugs were the cause.

In a subsequent study, Simpson *et al.*[18] attempted the very difficult task of replicating Bedford's findings in a prospective study. As formal preoperative psychological assessment was part of Simpson's study design, only elective patients could be included. After considerable efforts, 678 elderly patients having surgery were evaluated, two-thirds of whom underwent general anaesthesia. This major undertaking yielded only one patient in whom there was good evidence that a permanent deterioration in mental function occurred immediately after anaesthesia.

These two reports[17,18] stimulated many psychometric studies of short- and long-term postoperative cognitive outcome. Tables 137.1 and 137.2 summarize the results of 17 such studies[19–35], which have looked at psychometric test performance in ageing patients before and after surgery. Follow-up periods have ranged from a few days to over 3 months, and many different types of psychometric tests have been used. Table 137.1 contains 13 studies in which older patients have been randomized to receive general or regional anaesthesia, while Table 137.2 summarizes four alternative study designs that have given an insight into the effect of age on postoperative cognitive problems. These include the ISPOCD1 study, which is discussed in detail below.

There are major methodological problems in carrying out clinically meaningful psychometric testing in elderly elective surgical patients[35]. These problems become almost insuperable in patients who are admitted as emergencies, and only two of the studies listed in Tables 137.1 and 137.2 considered non-elective patients. Unfortunately, there is ample evidence that it is non-elective patients who have the highest incidence of postoperative mental events, although in many emergency cases non-anaesthetic factors, such as acute illness, are probably more culpable than anaesthetic drugs.

The 13 studies in Table 137.1 compared the psychometric effects of general anaesthesia with those associated with "regional" techniques (local, spinal or epidural anaesthesia). Four of the earlier studies reported that the general anaesthetic group performed more poorly, but even here the effect was seen only during the immediate postoperative period.

The studies that make up Tables 137.1 and 137.2 contain a wealth of detail, but some broad overall conclusions can be drawn. As might be expected, the major effects on mental function are seen in the first postoperative day, but some of the studies report minor effects on some tests for up to 7 days. The studies that specifically compared young and old patients found that the older group performed slightly worse than the younger during the early postoperative period.

While *short-term* mental impairment following surgery is of importance, especially in these days of increasing day surgery provision[36], it is *long-term* mental impairment that is feared most by patients, their relatives and their doctors. In the first edition of this textbook[37], comfort was drawn from the fact that the best-designed of the long-term studies up to that date had reported no objective evidence of mental impairment 1 month or more after surgery. It was noted, however, that 16% of the patients of Jones *et al.*[21] had complained of subjective changes in memory and concentration at 3 months after surgery, and that these authors had commented that these patients might have had minor intellectual changes which had been missed by the chosen psychological tests. Since that time, the study of Williams-Russo *et al.*[19] has similarly reported long-term postoperative cognitive changes in 5% of patients. Further concern has been raised by the finding of long-term cognitive deficit in the ISPOCD1 study[32], which, unlike the Williams-Russo *et al.* study, included a group of non-operated control patients to meet the criticism that some of the effects reported in early studies reflected the progression of coincidental dementia, unrelated to surgery or anaesthesia. The ISPOCD1 study and its successor, ISPOCD2, will now be described in some detail.

The ISPOCD Studies

The first International Study of Post-operative Cognitive Dysfunction (ISPOCD1) collected data between 1994 and 1996 on 1218 patients aged 60+ who were undergoing major non-cardiac surgery in 13 hospitals in eight European countries and the USA[32]. This was a major undertaking, which was intended to answer many of the questions about early and late postoperative cognitive dysfunction in older people that had been raised in the literature over the previous 30 years. In the event, the results of the ISPOCD1 study, published in 1998[32], still left several unanswered questions which are being addressed in a further study (ISPOCD2), which is due to report in May 2001.

Table 137.1 Randomized studies comparing the psychometric effects* of general anaesthesia (GA) and regional anaesthesia** (RA)

Reference	Number of patients	Age (years)	Type of surgery [anaesthesia]	Timing of postoperative tests	Main findings	Difference between GA/RA?	Long-term cognitive deficit?
19	262	> 40, median 69	knee replacement (TKR) [Epidural vs. general anaesthesia]	7 days, 6 months	Delirium occurred in 11%. Complex changes in psychometric tests, but there was a general reduction at 7 days with return to baseline (or better) by 6 months. However, Trail Making A and B worse at 6 months	No	5% Showed significant deterioration at 6 months, but there were no untreated controls
20	169	65–98	Cataract [GA vs. local]	1, 14 days, 3 months	Reduction in verbal recall/learning, psychomotor speed and tactile naming on day 1 only	No	No
21	146 patients, 50 controls (patients on waiting list)	60 +	hip (THR) or knee replacement [GA vs. epidural]	3 months	No decreases on tests in patients or controls at 3 months. Tests included Choice Reaction Time (which *increased* in GA group), object learning, digit copying, critical flicker fusion, and cognitive difficulties scale	No	No *measurable* decrease, but 11/56 GA and 10/60 RA patients thought concentration and memory were poorer
22	64	60–86	TKR [GA vs. spinal]	3 months	Tests tended to improve at 3 months (? practice effect)	No	No
23	40	60–80	Transurethral resection of prostate (TURP) [GA vs. epidural]	4, 21 days	Day 4 only: reduced paired associate learning, visual memory and visual recall	No	No
24	105	25–86	Hysterectomy, TURP, THR/TKR	1–7 days, 3 months	Modest decrease in memory and cognitive tasks in early period. Later tests usually better than baseline	No	No
25	30	50–80	THR [GA vs. spinal]	1, 2, 7 days	Spinal group had worse word recall/recognition on day 1, no differences on later days	Yes	Not tested
26	44	60–93	TURP, pelvic floor surgery [GA vs. spinal]	6 h, 1, 3, 5 days, 1 month	At 6 h GA group had reduced Mini-Mental Status. No later differences on Mini-Mental or Geriatric Mental Assessment	Yes	No
27	57	65–92	Hip fracture [GA vs. epidural]	1, 7 days	38–50% Delirium (even though patients excluded if Organic Brain Syndrome Scale abnormal preoperatively)	No	Not tested
28	40	> 60	Hip fracture [GA vs. spinal]	7 days, 3 months	Abbreviated Mental Test *improved* at 1 week (no other test was used)	No	No
29	30	> 60	THR [GA vs. epidural vs. both]	2, 4, 7 days, 3 months	Assessment by psychologist. Various tests impaired for 2–4 days, then recovered	No	No
30	60	> 65	Cataract [GA vs. local + sedation]	7 days	Wechsler Memory Scale and Luria tests reduced relative to baseline	Yes (LA *worse*, Luria only)	Not tested
31	60	56–84	THR [GA vs. epidural]	1, 3, 7, 12 days	No formal psychological tests; 7 out of 31 in GA group (0 out of 29 epidural group) said to have mental changes in first 7 days	Yes	5 out of 31 GA patients reported mental changes 4–10 months after surgery

*For full details of psychometric tests, see references 4, 37.
**Regional anaesthesia includes local, spinal and epidural anaesthesia.

A key feature of the ISPOCD studies has been the use of the European psychometric test battery (EUPT battery), which has been designed as a sensitive and standardized research tool for the detection of postoperative neuropsychological deficits and which can be administered over a 45 min period. This battery uses the Mini-Mental State Examination (MMSE) as a screening test, with patients scoring 23 or less being excluded from further testing. The remaining tests (used in ISPOCD1 and in a slightly modified form in ISPOCD2) comprise a Verbal Learning Test, a Concept Shifting Test, the Stroop Colour Word interference test, a Letter Digit substitution task, a four boxes test, the Broadbent Cognitive Failure Questionnaire, and a Zung Depression Score Questionnaire (the Geriatric Depression Scale being used in ISPOCD2). The definition of postoperative cognitive dysfunction (POCD) has been reached by comparing changes in the normalized (Z) scores of individual patients with age-matched controls who were not undergoing surgery, who were studied at the same time intervals.

ISPOCD1[32] was particularly concerned to test the hypothesis that hypoxaemia and/or hypotension were causative factors in POCD. Accordingly, oxygen saturation was measured by

Table 137.2 Other studies of general anaesthesia and postoperative cognitive dysfunction

Reference	Age (*n*)	Type of surgery	Type of psychometric tests	Timing of post-operative tests	Results	Long-term change?	Comments
32	> 60 (1218 patients, plus 321 community controls)	Major non-cardiac surgery (if preoperative Mini-Mental Status was 24 or more)	EUBT (see text for details)	7 days 3 months	Postoperative cognitive dysfunction (defined after comparisons with untreated controls) in 25.8% at 7 days and 9.9% at 3 months (controls 3.4%, 2.8%)	Yes	Age, duration of anaesthesia, less education, and respiratory and other complications (but *not* hypoxaemia) correlated with dysfunction at 7 days Age was *only* risk factor correlating with cognitive dysfunction at 3 months
33	48–88 (112)	Transurethral resection of prostate	Choice reaction time	1, 2, 3 days	Increased variability in choice reaction time, day 1 only	Not tested	Increased variability associated with previous low CAPE (Clifton Assessment Procedure for the Elderly), extent of surgery, postoperative pain/sedation
16	25–83 (40)	Cholecystectomy	Mini-Mental, digit symbol/span, trail making	1, 2, 3, 4 days, 1 month	Changes on day 1 only: digit symbol (all), trail making (old only)	No	Concluded there was no major difference in rate of recovery between young and elderly groups
34	Two groups: young, mean age 50; old mean age 69 ($n = 85$)	Orthopaedic, gynaecological and general surgery	17 Questions (orientation/concentration), plus object learning test	2 days	Memory deficits (young and old). Orientation and concentration deficits (old only)	Not tested	Correlation between postoperative deficits and poor preoperative cognitive function

continuous pulse oximetry before surgery, throughout the day of surgery, and for the next three nights. Blood pressure was recorded by oscillometry during the operation and every 30 min for the rest of the operative day and night. Patients received general anaesthesia but no restriction was placed on anaesthetic or surgical technique, which conformed to local practice in the study centers. However, to avoid the cerebral vasoconstrictor effects of hypocapnia, capnography was a requirement during surgery, so that normocapnia could be maintained.

Analysis of the data from ISPOCD1[32] showed that 25.8% patients had POCD 7 days after surgery and that 9.9% of all patients still had evidence of POCD on the repeat neuropsychological tests carried out at 3 months (corresponding values for controls were 3.4% and 2.8%). Contrary to expectations, no relationship was found between hypoxaemia and/or hypotension and the development of early or late POCD. Indeed, despite analyses of the effects of more than 25 other clinical parameters, only age showed a statistically significant correlation with late POCD. Age was also positively correlated with early POCD, as were duration of anaesthesia, a lesser level of education, a second operation, postoperative infections and respiratory complications.

The overall conclusion of the ISPOCD1 investigators[32] was that their study had demonstrated a measurable degree of post-operative cognitive change in a minority of older patients 3 months after surgery (in about 10% of patients vs. about 3% of non-operated controls) and that the risk increased with age. However, the expected relationship between hypoxaemia and/or hypotension and POCD did not emerge in the study. It was also disappointing that, despite a large number of statistical analyses, the study failed to find any specific risk factors that were amenable to therapeutic or preventive intervention. In addition, the hope that the study would give better insight into the pathophysiology of POCD was not fulfilled.

Because the ISPOCD1 study did not provide the expected answers in regard to the prevention or treatment of POCD, ISPOCD2 is now under way, coordinated from Copenhagen by J. T. Moller and L. S. Rasmussen. I am very grateful to Dr Christopher Hanning, a member of the ISPOCD2 steering committee, for the following information. ISPOCD2 comprises a linked group of multicentre projects which will ask a dozen major research questions in a variety of patient populations. A major task of ISPOCD2 will be to follow up patients for a prolonged period, to see whether the 3 month postoperative neuropsychological changes persist, and to test whether these changes produce measurable effects on Activities of Daily Living and Quality of Life. Other research tasks addressed by ISPOCD2 include: an investigation of the effects of outpatient anaesthesia; a comparison of the effects of regional anaesthesia with those of general anaesthesia; a comparison of POCD incidence in patients aged 40–60 years and in older patients; a test of the hypothesis that there might be a genetic predisposition to POCD related to the apolipoprotein E allele, which is known to have an association with the development of Alzheimer's disease; a correlation of blood levels of benzodiazepines and their metabolites with the development of POCD; an examination of the role of cholinergic and other neurotransmitters in POCD, using an animal model and positron emission tomography (PET) in humans; the study of possible protected effects of ondansetron; a study of structural cerebral changes by both MRI and SPET scanning; correlations of POCD with neurone specific enolase and protein S100; and the investigation of the relationship between POCD and "stress", particularly prolonged hypercortisolaemia.

CONCLUSION

While the great majority of older people undergoing surgery and anaesthesia will emerge without any cognitive sequelae, absolute guarantees cannot be given. Indeed, since the last edition of this book, the previous consensus that routine anaesthesia *per se* had essentially no long-term effect on postoperative function has been challenged by large carefully designed studies. It is to be hoped that the ISPOCD2 study and similar large-scale investigations will allow us to give more authoritative advice to older patients undergoing surgery in the first decade of the twenty-first century.

Nutritional State

D. N. Anderson[1] and M. T. Abou-Saleh[2]

[1]*Mossley Hill Hospital, Liverpool, and* [2]*St George's Hospital Medical School, London, UK*

Dietary surveys of elderly people in the UK and Sweden have shown that a substantial proportion of subjects had intakes below recommended standards. Two US National Health and Nutrition surveys showed that 50% of the population, especially the elderly, were deficient in one or more nutrients. In 1979, a Department of Health and Social Security (DHSS) survey in the UK suggested that 7% of those aged 65+ may be undernourished and twice this proportion of those aged 80+[1]. A survey in Sydney found that intakes of nutrients by old people in Australia were similar to those recorded in the UK[2] and concluded that a significant proportion of this population may be at risk. Depending on definitions and diagnostic criteria, undernutrition in community-based elderly people is in the range 0–82% and in hospital 5–63%[3].

High-risk groups include the housebound and those with impaired cognitive function, a history of depression, chronic pulmonary disease and partial gastrectomy. Poor dentition, swallowing difficulties and not having regular cooked meals are further factors placing people at greater risk of malnutrition.

The reasons for poor nutrition are various and the cause often multifactorial. Nutritional deficiency rarely occurs in isolation but is usually consequent upon ill-health or poverty. The UK DHSS survey of 1968[4] found 3% of 1000 elderly people to be malnourished, largely because of untreated underlying medical conditions or socioeconomic disadvantage. Poor financial reserves, isolation, physical handicap, dental problems and mental disorder all contribute, and the effects of disease, disability and ageing can combine to change a marginally sufficient diet into a grossly deficient one[5]. The prevalence of malnutrition is certainly higher in old people than in younger groups, attributable in the main to higher proportions of the elderly living in poverty and a greater prevalence of disease in old age. The diet of lower socioeconomic groups provides cheap energy and is lower in essential nutrients, such as calcium, iron, magnesium, folate, other B vitamins and vitamin C[6].

Methods of food preparations and a lack of knowledge about daily requirements are also important. It must be cause for concern that elderly people in residential care and long-stay hospital wards have been found to be at greatest risk of undernutrition, although naturally, they represent some of society's oldest and most frail individuals. Burns *et al.*[7] found a group of elderly dementing people in institutional care to be more undernourished than those living alone in the community, even though they were no more cognitively impaired. Kennedy and Henderson[8] found the risk of nutritional deficiency to be greater in residential than in hospital care.

Classical single deficiency states are rare in the UK and USA elderly, but there is a strong suspicion that suboptimal nutrition frequently contributes to ill-health in old age. Malnutrition leads to lowered physical strength, greater inactivity and risk of accidents, a weaker immune system and osteoporosis[6]. Poor vision, macular degeneration and cataracts are being linked to diets lower in fruit, vegetables and antioxidants[9]. Subclinical vitamin deficiency is more common in the elderly, particularly those with psychiatric disorders. Hancock *et al.*[10] compared nutritional indices of healthy and mentally ill elderly women and reported lower levels of vitamin C, riboflavine and pyridoxine among the elderly mentally ill. Of 255 psychogeriatric admissions with organic and functional disorders, Bober[11] found low concentrations of ascorbic acid in over 50% and low plasma folate in approximately 20% of subjects.

A study in England conducted by the Health Advisory Service 2000, commissioned by the Secretary of State for Health, identified feeding and nutrition in acute hospital wards for the elderly to be deficient in many respects[12]. Malnutrition is largely unrecognized in British hospitals and is particularly common in old age[13]. In one study of adult hospital admissions, the overall average weight loss was 5.4% and was greatest in those initially most undernourished. Nutritional status was infrequently recorded[14].

There are difficulties in the assessment of nutritional status and establishing accepted recommendations for daily requirements. Commonly used reference data in the UK may not be appropriate for all populations of elderly people, and contemporary reference data that are widely applicable, with clinically defined criteria for undernutrition, are needed[15]. Furthermore, it is not clear how illness may alter these requirements. The assessment of nutritional status is complex and a single measure usually insufficient; however, anthropometric measurements are the preferred clinical tool for routine use and can provide practical and valid indices of nutritional status[16]. Preferably, evidence of undernutrition is established from a combination of history and examination, anthropometry, haematological and biochemical indices[17,18]. Of the 10 risk factors described by Davies[19], depression, loneliness and alcoholism feature, in addition to social variables and factors reflecting dietary intake and weight change. Bender[20] points out that tables of nutrient requirements are of limited value, as individuals' energy and nutritional needs vary.

Although discussions of nutrition tend to focus on deficiencies, it should be remembered that the commonest nutritional disorder affecting old people in developed countries is obesity. The problem of obesity, which is often difficult to remedy, has established implications for physical illnesses such as hypertension, heart disease, diabetes mellitus and arthritis. Drugs used in the treatment of mental illness in old age not infrequently lead to weight gain.

Low body weight is associated with an increased mortality of elderly people living at home[21] and admitted to hospital[22]. Poor nutrition increases the risk of falls and hip fractures[23] and is associated with excess winter deaths[24], the development of pressure sores[25] and infections[26].

Undernutrition may arise from quantitative and qualitative dietary inadequacy, leading to mixed nutrient deficiency. If old people meet their energy requirements by taking a good mixed diet their needs for nutrients will be met. Some elderly people lead such sedentary lives that their energy requirement is very low[27] and they become at risk of taking inadequate protein, minerals and vitamins. As life becomes more sedentary and energy intake declines, then diet needs to become more nutrient-dense. Asplund *et al.*[28] found that 30% of 91 patients, with a variety of diagnoses, admitted to psychogeriatric inpatient care were undernourished. A high prevalence of thiamine deficiency has been reported, especially among the housebound, solitary and confused[29] but also among admissions to psychiatric units[30]. Alcoholism is commonly associated with deficiencies in thiamine but also riboflavine, pyridoxine, vitamin B_{12} and folic acid. Subnormal levels of vitamin C, thiamine and pyridoxine were found by MacLennan *et al.*[31] in long-stay elderly patients who were also protein-deficient. Inadequate intake of vitamin C has been shown for 75% of elderly men and over 80% of women, not always reflected by leucocyte ascorbate levels or laboratory parameters[31,32]. Vitamin D levels have been shown to be very low in long-stay elderly populations[33], almost certainly secondary to inadequate exposure to sunlight[34]. Evidence of multiple vitamin deficiencies has been reported in elderly day hospital attenders and residents of local authority residential homes[8].

Vitamin deficiency is rarely sought in clinical practice, when only B_{12} and folate estimations tend to be performed with any regularity. Yet any deficiency, particularly involving the B group, can present with apathy, anorexia, weight loss, mood changes, acute and chronic confusional states and occasionally hallucinations and paranoia[35]. Depression and alcoholism seem to be the characteristic disorders associated with vitamin B and folate deficiencies, while organic psychosyndromes are typical of B_{12} deficiency[30]. Thiamine deficiency can produce a wide variety of mental disturbance and ascorbic acid deficiency is usually linked with apathy and depression. Irritability, aggressive behaviour and personality change were reported in healthy volunteers undergoing thiamine restriction[36]. Vitamins and minerals are intimately involved in cell metabolism, neurotransmitter synthesis and cell membrane stability. Mineral and electrolyte deficiencies, including iron, calcium, potassium and magnesium, are also common findings among elderly populations[3], with obvious implications for health.

TREATMENT

The immediate significance of single deficiency states is confined to few specific circumstances, e.g. thiamine and the Wernicke–Korsakoff syndrome, B_{12} and folate with certain dementias and pseudodepressive states. In most instances, the import of nutritional status is less obvious and the effects of deficiency probably more subtle. Although nutritional supplementation is unlikely to be curative in these situations, there are few studies of the effects of nutritional intervention in elderly populations with mental disorder and more information is needed before drawing firm conclusions. While the real significance of nutritional manipulation is awaited, a pragmatic position recommending dietary supplementation and adjustment with efforts to prevent undernutrition is advised.

In many circumstances, treating an underlying mental disorder or physical illness effectively will restore appetite and drive, thereby correcting deficiency by the resumption of a normal diet. The admission of a confused elderly person to hospital or care may provide the opportunity to re-establish a normal eating pattern. In specific deficiency disorders the prescription of necessary supplements will be an essential part of treatment. The possibility that nutrient supplementation may enhance the response to conventional psychotropic medication[37] is an interesting possibility that requires further exploration.

The correction of deficiency does not necessarily involve prescribed medication but may be possible by simple measures, such as supplementing the diet with fruit juices to provide more vitamin C. Low levels of vitamin D are found in up to 40% of the elderly living at home or in hospital. Diet is an inadequate source of vitamin D, which depends on exposure to ultraviolet light for its formation. A greater exposure to natural sunlight is the most important preventive measure, but because the elderly are at special risk it is recommended they receive vitamin D supplementation to achieve a daily intake of $10\,\mu g$[38].

The overwhelming priority in the management of undernutrition among the elderly population is prevention. A major impetus must ultimately come from a change in public policy that improves the elderly person's social, material and financial position in society and ensures the efficient provision of services to those in need.

The market-led approach to nutrition that operates in many food-rich countries has been found to increase the disparity between the nutrition and health of the rich and poor[39]. The provision of domiciliary care services is inequitably distributed, often inefficiently organized and frequently determined by demand rather than need[40]. Consequently, invaluable services, like meals-on-wheels and home helps (often the only people to provide food to isolated mentally ill old people), may not reach those most at risk. Little attention or imagination has been given to the meals service, potentially an important resource, which suffers from a complex, multi-agency organization, inflexibility in delivering meals of a type or at a time to suit individuals and often arriving cold. Only half the recipients find the meals at least moderately satisfactory[41] while 15% never eat them and 15% eat only half those delivered[42]. There is little evidence that they are targeted at those most at risk of undernutrition and some evidence that the meals, themselves, are nutritionally inadequate[40]. This has led some to suggest that the service acts only as a symbol of concern for elderly people[43].

Often the supervision of meal times is as important as the meal itself. Confused elderly people may eat voraciously in the company of their family yet put meals aside when left to eat alone. Altering the timing of home help or family visits or attendance at a day centre or luncheon club may be the intervention required.

The prevention of undernutrition may be possible by simple measures, e.g. providing meals in a form that is appealing and easily edible. Kennedy and Henderson[8] demonstrated the importance of noting the food returned after meals by the elderly in residential care. Fruit, vegetables and meat were often left because they were difficult to chew. For seriously impaired individuals, maximizing food intake during the times of day when cognitive abilities are at their peak can improve dietary intake[44]. The time allowed for meals is normally less in institutions than at home[45], meal times are inflexible and little consideration is given to personal choice. Some patients will take food from family members and not care staff, or only from certain members of staff. Obviously adequate staffing levels will affect success when large numbers of disabled or resistive patients are eating together.

The recent practice in UK hospitals of extending menus to include less traditional dishes may be appreciated by the young, but experience suggests many elderly people are happier with local dishes and attempting radical alterations of lifelong dietary habits

can be difficult and may be counterproductive. Changes of this sort may actually reduce the opportunity to provide a nutritious diet to elderly hospitalized patients at a time when it is most needed. Fresh fruit is often difficult to obtain in institutions and modern methods of mass food preparation have been criticized. It may not be appreciated that less mobile elderly people have a fast protein flux that requires a higher, not lower, daily requirement for protein[17,18] and the protein intake of long-stay elderly patients can be inadequate[31].

Poor dentition is associated with undernutrition[46] and the fitting of dentures to old people in institutional care has been shown to increase the consumption of raw vegetables[47]; 78% of independent elderly patients examined by MacEntee *et al.*[48] believed their oral health to be good but only 17% had clinically healthy mouths. A study of hospitalized patients aged 61–99 years found that 60% had disease of the oral soft tissue[49].

Medication can impair the absorption and reduce the availability of essential nutrients, impair appetite, cause dry mouths and constipation or directly promote the loss of minerals, as with diuretics and potassium[50].

For those living in the community, preventive health care with early recognition and treatment of illness is essential. The elderly population may benefit from greater education and advice about healthy and affordable eating, issues normally targeted at younger age groups. The judicious use of fruit juices, frozen vegetables and some convenience foods might ease the burden of food preparation. Realizing that visual impairment and arthritic joints can prevent shopping and the opening of packets and tins may point the way to practical interventions, such as the provision of domestic aides or arranging for someone to collect shopping. One survey found that 22% of elderly people who had difficulty opening screw-top jars had to ask non-household members to do it for them[51]. The teaching of culinary skills is particularly relevant to the older bereaved male who never cooked when his wife was alive. Men, although age-for-age fitter than women, are twice as likely to say they are unable to cook a main meal[52].

In the modern era shops themselves are often large, impersonal, confusing places and sited some distance from home, making effective shopping difficult for physically and mentally disabled people. Low income and disability not only restricts ability to afford a protective diet but also limits access to retailers where healthy food can be purchased more cheaply. Local shops are less prevalent and can be significantly more expensive than more distantly sited supermarkets[53].

Finally, unless people are aware of the possibility of undernutrition and able to make an assessment, little progress will be made for the sick and vulnerable. Sadly, doctors and nurses frequently fail to recognize undernourishment because they are not trained to look for it[54] and medical students' knowledge of the issue of nutrition is poor[55]. Improved education is greatly needed. The Royal College of Nursing[56] provides clear guidelines for the assessment of nutritional status in older people.

CONCLUSION

A great deal needs to be known about the fundamentals of diet, nutrition and mental health in old age. The evidence connecting nutrition and morbidity suggests this is an area of importance to all professionals working with elderly people and a strong case could be made for the regular involvement of a dietician in the psychogeriatric team.

Establishing roles for nutritional intervention offers prospects of simple and economic measures that may improve the treatment and prognosis of mental disorders in old age, enhance clinical recovery and reduce morbidity.

At the present time, it cannot be claimed that vigorous dietary intervention offers curative treatment for mental illness but attention to diet may, at least, reduce the physical complications of mental disorder, hospitalization and ageing. However, there is accumulating interest in the role of antioxidants in the treatment of dementia [see Nutritional Factors in Dementia] and the possible significance of omega polyunsaturated fatty acids for maintaining the development and integrity of neuronal function has obvious relevance to severe mental illness[57]. Schizophrenic patients taking additional omega 3 polyunsaturated fatty acids may experience milder symptoms[58] and a recent study of community residing schizophrenic patients aged 20–79 years demonstrated nutritional deficiency, despite most being overweight, with a high intake of saturated fat and low intake of antioxidant[59].

Further exploration of the relationship between dietary constituents and the course of mental illness may yet yield information significant to the management of mental illness in old age.

Mental Illness in Nursing Homes and Hostels in Australia

David Ames

Royal Melbourne Hospital, Parkville, Victoria, Australia

Australia has a population of over 19 000 000 people. Less than 2% are descended from the original inhabitants and over 12% are aged 65 +. The probability of using nursing home care at some point in one's life is currently estimated to be around 25% at birth, rising to 60% from when aged 80 and 95% from when aged 90. As the life expectancy of those aged 65 now extends well beyond 80 years, the majority of older Australians can expect to have some experience of residential care before their lives end[1]. In recent years Australian government policy has directed funding away from residential provision towards community care, and has acted to blur the distinction between nursing homes providing full nursing care 24 h/day and hostels that offer accommodation, meals, supervision and some assistance with activities of daily living but do not furnish residents with 24 h/day nursing care[2,3].

In 1993 there were 74 494 nursing home beds in Australia and by 2011, if the intended planning ratio of 40 beds/1000 persons aged 70 + has been reached, there will be 78 600 beds[4]. The policy direction for hostels is to increase the level of supply from a 1993 level of 40 places/1000 persons aged 70 + to a projected level of 52.5 by 2011. There were 54 429 hostel places in Australia in 1993.

Mental Illness in Nursing Homes and Hostels in Australia

David Ames
Royal Melbourne Hospital, Parkville, Victoria, Australia

Australia has a population of over 19 000 000 people. Less than 2% are descended from the original inhabitants and over 12% are aged 65+. The probability of using nursing home care at some point in one's life is currently estimated to be around 25% at birth, rising to 60% from when aged 80 and 95% from when aged 90. As the life expectancy of those aged 65 now extends well beyond 80 years, the majority of older Australians can expect to have some experience of residential care before their lives end[1]. In recent years Australian government policy has directed funding away from residential provision towards community care, and has acted to blur the distinction between nursing homes providing full nursing care 24 h/day and hostels that offer accommodation, meals, supervision and some assistance with activities of daily living but do not furnish residents with 24 h/day nursing care[2,3].

In 1993 there were 74 494 nursing home beds in Australia and by 2011, if the intended planning ratio of 40 beds/1000 persons aged 70+ has been reached, there will be 78 600 beds[4]. The policy direction for hostels is to increase the level of supply from a 1993 level of 40 places/1000 persons aged 70+ to a projected level of 52.5 by 2011. There were 54 429 hostel places in Australia in 1993.

By early 1999, 140 000 nursing home and hostel places were available in Australia, with 2500 new places being established each year, mostly in hostels[1]. These places serve 2 154 000 Australians aged 65+, of whom 129 600 were thought to have dementia in 1995[5].

Few residential facilities offer specialized care for the elderly with mental illness. In the State of Victoria a small number of nursing homes subsidized by the State Government, called "Psychogeriatric Nursing Homes", offer specialized care to elderly people with mental health problems (usually dementia), associated with behaviour too challenging to be managed in mainstream facilities. Long-term care in large mental hospitals and state geriatric centres is virtually a thing of the past[6].

A small number of researchers have examined the prevalence of psychiatric disorders among elderly people in Australian nursing homes and hostels. At least 50% and possibly 80% of nursing home residents have dementia[5–7]. Around 40% of hostel residents have cognitive impairment consistent with dementia[6,8]. Although the more severely demented residents cannot be assessed, it is unusual for an assessable resident to have no symptoms of depression at all and at least 10% suffer a depressive disorder at any time[9,10]. No detailed statistics are available for the numbers of individuals with schizophrenia and related disorders living in nursing homes in Australia. The four specialist psychogeriatric nursing homes in the author's own catchment area, which serve a population of over 120 000 elderly, have 120 beds, of which around 30 are occupied by individuals with a primary diagnosis of schizophrenia and related disorder. Most of these residents are former long-term inmates of psychiatric facilities, so this percentage is likely to fall in future as fewer individuals with schizophrenia will experience long-term incarceration. The percentage of individuals with schizophrenia and related disorders in ordinary nursing homes and hostels would be far lower than this.

Despite high levels of depression and dementia, a recent study by Reberger, Hall and Criddle[11] revealed that entering a hostel can lead to an overall improvement in quality of life, although the size of the study was small, assessing only 50 subjects.

General practitioners are responsible for the medical care of the vast majority of individuals in nursing homes and hostels, as few residents see a psychiatrist once, let alone on a regular basis. A well-conducted study of over 2000 residents in 46 Sydney nursing homes revealed very high levels of psychotropic drug prescribing to this population[12]. Psychotropic drugs were taken regularly by 58.9% of residents and another 7% were prescribed such drugs on an "as-required" basis. Antipsychotic drugs were taken regularly by 27.4% and on an "as-required" basis by a further 1.4%. These drugs were more likely to be given to residents with greater cognitive impairment and more disturbed behaviour. Benzodiazepines were prescribed to 32.3%, hypnotics to 26.6% and antidepressants to 15.6%. At least half the antidepressant doses were subtherapeutic.

As in other countries, one major concern has been the underdetection and undertreatment of depression in residential care. An innovative and painstaking series of studies were done in North Sydney by Llewellyn-Jones *et al.*[13]. This project included a randomized, controlled trial, with control and intervention groups studied sequentially and blind follow-up after 9.5 months of 220 depressed residents in a large residential facility. The interventions consisted of multidisciplinary consultation and collaboration, training of general practitioners and carers in the detection and management of depression, and depression-related health education and activity programmes for residents. The control group received routine care. There was significantly more movement to less depressed levels of depression, as measured by the Geriatric Depression Scale (GDS) at follow-up, in the intervention than the control group. Multiple linear regression analysis found a significant intervention effect after controlling for possible confounders, intervention groups showing an average improvement of 1.87 points on the GDS. Although the impact of this study on total GDS scores was not huge, small movements in depressive symptomatology in populations are likely to be associated with significant decrease in morbidity among some individuals. In the past it has been hard to show that intervention programmes in these populations can be efficacious[10], but the work of Llewellyn-Jones' team suggests that the future may not be as bleak as some of us had feared.

There is no doubt that mental illness is common among individuals who live in residential care in Australia. The challenge for our health professionals is to improve the detection and management of these conditions. A multifaceted approach is required, with improved medical education for both undergraduates and general practitioners, education for care staff and an overall improvement in the quality of residential provision for older people. Slow, relative economic decline in Australia[6], which continues apace, will make this a difficult challenge to rise to, but Australia's track record in this area suggests that the goal is not an unachievable one.

Caregivers and Their Support

Kathleen C. Buckwalter[1], Linda Garand[2] and Meridean Maas[3]

[1]*University of Iowa,* [2]*University of Pittsburgh School of Nursing, and* [3]*University of Iowa College of Nursing, USA*

As this book clearly demonstrates, Alzheimer's disease and related dementias (ADRD) are tragic, debilitating, chronic illnesses with an unpredictable clinical course. The tragedy is compounded by the consequences associated with caregiving, such as impaired mental and physical health, and disruption of normal activities and social relationships of the caregiver. Cognitively impaired elders are often placed in long-term care facilities when family caregivers are either no longer available or are unable to continue home caregiving because of inability to manage behavioral problems, unremitting stress or caregiver illness. This chapter highlights the importance of the caregiver role, as well as costs to, and support for, family caregivers in the community and throughout the process of relocating the recipient to an institutional setting. Research on caregiver stress and the positive and negative effects of caregiving is reviewed, with attention to both psychosocial and physiological outcomes, as well as variables that may moderate stressors inherent in the caregiving role.

IMPORTANCE OF THE CAREGIVER ROLE

Most older adults requiring assistance reside in the community, including those with dementia[1]. The main reason why persons with dementia are able to reside in the community is because they receive care from their families[2]. Of the more than 4 million Americans with ADRD, over 70% are cared for by family members, and spouses typically are the primary caregivers[3].

Families play a paramount role in the provision of care to persons with dementia and most families want to retain the role of caregiver, since their efforts can forestall institutionalization[4]. Consequently, dementia caregiving has emerged as one of the most serious healthcare issues facing our society today[5].

Who Are Family Caregivers?

There is no precise definition of family caregiving to guide researchers and health professionals[6,7]. Caregiving is a truly heterogeneous concept. Family members define caregiving and care-receiving differently, depending upon their relationship to the care recipient, gender, and whether or not residence is with the care recipient.

Informal caregiving typically falls to women, who provide 72% of family caregiving, with adult daughters providing 29% and wives 43%[8]; 80% of caregivers of persons with dementia are women, 55% are spouses, 35% are adult offspring and 5% are siblings; the remainder are other relatives or paid providers. Thus, family caregiving is more often a career for women[9]. Wives and daughters provide more activities of daily living (ADL) and instrumental activities of daily living (IADL) assistance to family members than do husbands and sons[10,11]. The preponderance of customary IADL assistance, viewed as "women's work", may result in the underestimation of the amount of caregiving of persons with dementia that is borne by women. However, there is evidence that men and women caregivers do not differ in length of caregiving service, hours per day spent in caring for relatives, and the perceived stress of caring for persons with dementia. Both perceive the most stress from dealing with behavioral problems, a common precipitant of institutionalization[12].

Public Policy and Cost Implications of Caregiving

Factors such as the aging of the population, the increase in dependency with age, and the scope of care provided by family members are especially important in understanding dementia care. Policy makers are increasingly aware of the fact that family caregiving is not cost-free. Caregivers incur numerous expenses, including home modifications, assistive devices, special food, high utility costs, and the cost of foregoing paid employment. This type of family support is estimated to be the equivalent of full-time work in about one-third of households providing dementia care. According to Day[13], the cash value of services performed by family caregivers far exceeds the combined cost of government and professional services to both the elderly who live in the community and those who live in institutions. Current estimates indicate that dementia family caregivers save the US healthcare system $196 billion/year[14]. Therefore, the importance of family caregivers will increase in the future, as the number of persons with dementia, and the costs of their care, increase.

Society at large benefits from the willingness and ability of families to care for their members who have dementia. Were it otherwise, persons with dementia would be institutionalized sooner and in larger numbers than is currently the case. This, in turn, would impose a far greater economic burden on society in providing long-term care to persons with dementia. Importantly, monetary estimates of dementia care in no way reflect the human costs of this devastating disease. Although family caregiving helps to contain costs to society as a whole, it often results in serious costs that are concentrated in caregiving families. As noted, the breadth and magnitude of these costs cannot be

calculated solely in economic terms. A large body of research has established that there are also profound effects of caregiving associated with poor health-related outcomes[15,16], as detailed later in this chapter.

CAREGIVER STRESS AND BURDEN AND ITS IMPACT ON CAREGIVER WELL-BEING

Concomitant with an increase in the prevalence of dementia is an escalation of the physical, emotional and economic burdens of dementia care. The concept of caregiver burden has been advanced as an all-encompassing term that refers to the financial, social, physical and emotional effects of caring for a family member with dementia[17]. Subjective burden, the caregiver's perception of the caregiving experience, is distinguished from objective burden, the actual changes in the caregiver's home situation[18]. Studies of the burden and stress of caring for a person with dementia, the resulting effects on mental and physical health outcomes of family caregivers, and the use of a variety of interventions to relieve adverse effects of caregiving burden are numerous. More recent research also has focused on the positive aspects associated with caregiving. Major findings from this body of research are summarized throughout this chapter.

Family caregivers of persons with ADRD experience numerous stressors that affect their health and well-being and precipitate institutionalization of the care recipient. Hence, the notion of "stress" has emerged as an important concept in dementia caregiver research[3]. The words "stress", "burden" and "distress" are often used interchangeably and are conceptualized to have similar meaning. George and Gwyther[19] defined the concept of dementia caregiver stress as: "the physical, psychological or emotional, social and financial problems that can be experienced by family members caring for impaired older adults" (p. 243). A variety of factors related to the symptoms associated with ADRD cause caregiver stress, including cognitive changes, loss of ability to function in daily activities, and behavioral disturbances. Spouses of persons with dementia may be at greatest risk for caregiver stress, since they are often elderly themselves. They may also have physical, psychological and financial challenges that could decrease their ability to respond to the demands of caregiving[20,21].

Models of Caregiver Stress

A number of theoretical frameworks have been used to guide studies of persons with dementia, their family caregivers and the effects of interventions on outcomes for both[22–28]. Stress models, in particular, have guided much of this research. However, models that predict a simple positive linear relationship between caregiver stress and the care recipient's level of impairment, such that caregivers providing assistance to the most behaviorally impaired persons report the greatest degree of burden, are not supported by the literature[29,30]. Rather, research indicates that caregiver stress is related to a number of care recipient and caregiver variables[31] and, as such, is a multivariate phenomenon.

Caregiver stress is moderated by many factors, including the caregiver's available resources, such as good physical health, social support, financial assets, coping abilities and personality traits[17]. Although a number of multivariate models of caregiver distress exist, space limitations preclude a review of extant models in this chapter. Rather, Vitaliano's model of distress[32] (Figure 138b.1) is set forth as an example of one useful model for understanding caregiver stress, because the variables of interest are well grounded in the caregiving and theoretical stress literature. Additionally, the model allows for the stratification of resources and vulnerability variables, which improves the chances of detecting relationships among stressors, resources and burden. In Vitaliano's model, both caregiver and care recipient variables, as well as psychological and social resources of the caregiver, are postulated to contribute to caregiver distress[32].

$$\text{Distress} = \frac{\text{Exposure to stressors} + \text{Vulnerability}}{\text{Psychological resources} + \text{Social resources}}$$

Figure 138b.1

The underlying assumption of research on caregiving stress and health outcomes is that the chronic stress of caregiving can lead, via vulnerabilities and limited resources, to psychological or physiological distress and illness. Vitaliano's model, for example, considers both psychological and biological markers of distress. Since data overwhelmingly suggest negative psychological consequences of caregiver stress, biological outcomes allow for assessment of the impact of the psychological distress on major physiological systems. As noted earlier, in caregiver research, multivariate models provide a more comprehensive picture of a caregiver's level of distress than either psychological or physiological variables alone[32]. Moreover, since Vitaliano's model of distress is expressed as a mathematical formula, a caregiver's level of distress (burden) may improve by decreasing undesirable variables or by increasing desirable variables.

STRESSORS ASSOCIATED WITH FAMILY CAREGIVING

Providing care for a family member with dementia is conceptualized as a chronic stressor[33]. Symptoms of dementia that the caregiver must contend with include (but are not limited to) progressive loss of: memory; judgment; the ability to interpret abstractions; language and motor deficits; and altered personality. Dementia results in profound cognitive and behavioral changes that culminate in an inability to perform instrumental activities of daily living, such as cooking and managing money, as well as basic activities of daily living (ADLs), such as bathing and toileting. The level of functional (ADL and/or IADL) impairment in care recipients was related to caregiver burden in one study[15], although a larger number of studies found no association between these variables[34–41]. Similarly, no evidence of a relationship exists between the care recipient's level of cognitive impairment and the caregiver's level of burden[34,35,39,42–44].

The course of the illness is unpredictable, as is the rapidity of decline; the only certainty is that the progressive cognitive impairments that characterize dementia will lead to an increasing need for supportive care and eventual death for the person with dementia. As the illness progresses, caregivers must be increasingly vigilant, since dementia patients may elope from home or injure themselves. In the final stages, patients are often completely dependent on their caregivers and need to be fed, bathed, toileted, transferred and dressed. Providing care to a person with dementia eventually becomes an all-consuming 24-h job, which may extend for 10 years or longer[45,46].

Behavioral Impairments in Care Recipients

The stress of providing 24 h care for a person with dementia is complicated by the development of episodic, problematic (or catastrophic) behaviors, when the person with dementia

becomes increasingly agitated, stressed or disorientated. The most commonly reported behavioral changes associated with dementia include neurovegetative symptoms (e.g. lethargy, social withdrawal), sleep disturbance, restlessness, wandering, assault, aggression, destroying property, verbally disruptive behavior (e.g. screaming), and inappropriate sexual behavior[47–51]. Behavioral problems are extensive in persons suffering from dementia, appearing in up to 67% of care recipients upon diagnosis[52], approximately 65% of demented persons who are institutionalized[49], and 70–90% of persons with advanced dementia[53,54]. They worsen with disease progression and may be related to fatigue, change, overstimulation, excessive demands or physical stressors[23]. Problematic behaviors appear to have a profound effect on caregivers' stress, and a number of investigators have concluded that these secondary symptoms are the most stressful to manage from a caregiving perspective[46,55,56]. In fact, the one care recipient characteristic that overwhelmingly predicts caregiver distress is the degree to which the care recipient demonstrates behavioral problems[15,34,37,44,47,50,51,57]. Many investigators also report that behavioral problems are strong predictors of institutionalization[47,57,58].

Other Factors that Influence Caregiver Stress

As noted earlier, researchers typically theorize the stress of caregiving as chronic because caregivers face many years of continuous exposure to the daily demands of caregiving. However, over the disease trajectory, the intensity and/or frequency of a caregiver's level of distress may vary widely. In an effort to better understand this variability, investigators have identified a number of factors associated with differing levels of morbid outcomes. Of special interest are a number of variables that appear to moderate, or render less harmful, the effects of caregiving among some individuals.

It appears that the amount of stress is influenced by whether or not the caregiver is co-resident with the care recipient, the abruptness of onset of the care recipient's disease, kinship relationship with the care recipient, and the coping strategies used by caregivers[59,60]. Seltzer and Li[61] found that daughters in later stages of caregiving had a more distant relationship with the care recipient and more subjective burden than daughters in the earlier stages, while wives evidenced the opposite pattern. Wives who had provided care for a longer time reported less burden and a closer relationship with their husbands if they perceived themselves to be in the later stages of caregiving. This finding is supported by the longitudinal studies of Schulz and Williamson[40], which suggest that caregivers have successfully adjusted to the rigors of caregiving and have learned to cope with the demands of the task. Evidence is mixed as to gender differences in the stress experienced once the caregiving role is undertaken[62]. Overall, the literature suggests that stress-related gender differences are more pronounced for caregivers of non-demented persons[12].

Social support has been examined both as a correlate of distress (a main effect) and as a modifier of the relationship between stressful experiences and distress (an interaction effect). In the broader stress and coping literature, social support has been a consistent moderator of stress-related outcomes[63], in that the presence of a strong social network and satisfaction with support is a powerful predictor of positive outcomes. Caregiving studies suggest a direct effect of social support on measures of burden, but evidence for a buffering effect has been less clear[32].

In sum, research has identified potential exposure (care recipient behaviors), vulnerability (e.g. age, gender, neuroticism, pre-existing hypertension) and resource (social support) variables that may either moderate or mediate relationships of caregiving psychological distress with measures of physiological impairment and illness. In spite of overwhelming evidence that caregiving is stressful, factors contributing to caregiver distress have not yet been delineated in a way that can effectively direct interventions or preventive strategies.

Dementia vs. Non-dementia Caregiving

There is evidence that family caring for a person with dementia is more stressful than caring for a person who is not demented or who has a physical limitation[64]. For example, Clipp and George[65] found that family members caring for a person with a dementia were more adversely affected by their role than family members caring for a relative with cancer. This relationship was not explained by the duration of the illness or by whether or not the caregiver was employed; however, younger spouse caregivers were more adversely affected than older caregivers. In a review of studies of caregiving in different types of illnesses, Biegel *et al.*[66] observed different patterns of distress. They concluded that the pattern of a peak distress period after initial diagnosis of acute onset, followed by a reduction in distress as time passes, was not observed in family caregivers of persons with gradual onset illness where no relief of distress was observed[67]. Co-resident caregivers of persons with stroke and of persons with dementia experienced similar degrees of burden and high levels of psychological distress, with psychiatric aspects of care resulting in greater stress than physical aspects[36].

POSITIVE AND NEGATIVE OUTCOMES OF FAMILY CAREGIVING FOR PERSONS WITH DEMENTIA

Although family caregiving of persons with dementia is usually regarded as stressful and includes a variety of negative outcomes, there is growing consensus that this is not always the case[68]. Some caregivers may receive satisfaction from the role[69,70]. Caregivers can gain satisfactions, emotional uplifts, gains in self-esteem and self-efficacy, optimism, and growth and meaning from their roles[71–74].

Impact of Caregiving on Health of Caregivers

Findings of studies are inconsistent as to the effects of caring for persons with dementia on family caregivers' mental and physical health. Some report no changes in emotional and physical health and a decrease in depression over time, although far more report worsening of depression and physical health[45,75–79]. Based on the findings from several studies[44,59,60,80] Wright[81] suggests that these inconsistent findings may be due to differences in coping strategies employed by caregivers.

Mental Health Outcomes

There is extensive documentation that caregivers are at risk for high levels of psychological distress (e.g. burden, stress, depression, perceived hassles). Despite gaps in the literature and differences in research methods used, caregiver studies have overwhelmingly pointed to the adverse effects that caregiving for someone with troublesome behavioral symptoms can have on the caregiver's mental health[16,82,83]. A number of studies have also revealed negative changes due to the strains of direct care, grief associated with the deterioration of their loved ones, social isolation, and the role changes of caregiving, including care at

home, following institutionalization, and when the care recipient dies[20,41,66,83–85].

Depression

Depressive symptoms are among the most frequently examined mental health effects on family caregivers of persons with dementia. Several studies document a greater prevalence of depression among caregivers of persons with dementia, compared to other age and gender group norms and persons who are not caregiving[43,86–88].

Prevalence rates of depressive symptomatology among caregivers range from 30%[87] to 46% among community caregivers[86]. Moreover, depression among caregivers is associated with intensity of their reactions to the patients' memory and behavior problems[89,90] and to other adverse outcomes, such as increased physical burden[36], subjective burden[91–93], and use of psychotropic medications[15,65].

Depression is also noted to be greater among females than males[10] and appears to increase over time among residential caregivers and decrease over time following institutionalization and bereavement[83,87]. However, younger spouse caregivers were found to have higher levels of depression than older spouses in a study of residential and institutional caregiving[94]. There were positive relationships between depression and health status and depression and days unable to work among residential caregivers, but only between physical health characteristics and health status among the institutional spouse caregivers, and no significant difference in depression between genders. Compared to non-caregiving men, male spouse caregivers have been shown to have higher levels of depression, respiratory symptoms and poorer health habits, but the groups did not differ on other measures of physical and mental health[95].

Although no subjects were clinically depressed, Wright[81] found spouse caregivers of demented persons to have significantly greater dysphoric moods than a comparison group of non-caregiving spouses, with sadness of subsequently widowed spouses significantly greater than for non-widowed spouses. Widowed spouses also had poorer health outcomes over time and used fewer positive coping strategies, regardless of whether they placed their loved one in an institution.

Anxiety

Several investigators incorporated self-report measures of anxiety into their studies of depression. Mohide *et al.*[96] found that 22/23 individuals found to have significant symptoms of depression also reported significant symptoms of anxiety. Similarly, Vitaliano *et al.*[30] found 35.4% of their sample to have significant symptoms of anxiety. Neundorfer[93] reported much lower rates of both anxiety (15%) and depression (25%) among her sample of caregivers, although their scores were somewhat higher than population norms for elderly individuals.

Overall, there is strong evidence suggesting that caregivers exhibit higher levels of psychiatric symptomatology than comparison groups. Yet caution must be exercised when interpreting the generalizability of these findings, since many of the samples may be biased toward the more distressed members of the caregiving community. For example, the majority of caregivers are recruited from local chapters of the Alzheimer's Association, caregiver support groups, or through referrals by healthcare professionals. Individuals who have little difficulty with the caregiving role or who are so distressed or constrained that they are unable to participate in supportive programs or visit healthcare professionals may be underrepresented in research.

Some authors have also questioned the clinical significance of psychiatric symptoms reported in caregiver distress studies. There remains a criterion problem of distinguishing normal distress from psychiatric illness[84]. Transient periods of grief, despair, helplessness and hopelessness may be much more common than a diagnosable depression among family caregivers. Becker and Morissey[84] argue that the severe and chronic stressors associated with dementia caregiving are unlikely to precipitate a major depressive disorder, except in predisposed individuals. They suggest that the depressive-like symptoms among caregiving spouses should be categorized under Code V: Conditions Not Due to a Psychiatric Disorder[84]. This view is consistent with the conclusion reached by Fitting *et al.*[97] who state: "It is our impression that most caregivers reporting depressive symptomatology are experiencing a 'transient dysphoric mood' and not major depression" (p. 250).

To summarize, the literature on mental health outcomes of caregiving is suggestive but not conclusive[98]. There is strong evidence for increased symptom reports for depression, anxiety and increased psychotropic drug use among caregivers in these studies, as well as support for increased clinical psychiatric illness among some caregivers.

Physical Health Outcomes

Most of the literature examining the physical effects of caregiving has used one or more indicators of caregiver health: (a) self-reported health status; (b) self-reported incidence of illness-related symptoms; (c) self-reported utilization of health-care services; (d) self-reported medication use; and (e) biological indicators as a measure of susceptibility to disease. Reported predictors of poor physical health outcomes for caregivers include older age, being a spouse rather than adult child or other relative, and being female rather than male[15,79]. Interestingly, a relationship between the positive aspects of caregiving and physical health has also been reported. Emotional uplifts in family members with coronary heart disease (CHD), who are caring for persons with dementia, mediates the severity of metabolic signs that predict CHD[99].

Although there are fewer reported studies, the psychoneurological and immunological effects of caregiving are receiving increased attention. A decrease in measures of cellular immunity, and more days of infection following long-term residential caregiving of persons with dementia compared to controls also has been demonstrated, with caregivers who reported less social support and more stress having the greatest adverse immune function effects 13 months later[87]. Alterations in physiological function as a result of exposure to stress have been found to increase the probability of illness[100].

Similarly, psychological stress can increase caregiver vulnerability to disease by compromising the integrity of the immune system[101]. Kiecolt-Glaser *et al.*[101] have examined depression and distress as immunological modifiers. Their research team has also documented poorer immune response, in particular changes in the percentages of helper T-lymphocytes and natural killer (NK) cells, in caregivers of persons with dementia, while controlling for nutritional intake and illness-related variables[101].

Caregivers in this study also reported nearly three times as many stress-related symptoms and higher rates of psychotropic drug use than controls, especially those who were living with the person with dementia. Other studies comparing psychotropic drug use in caregiving and non-caregiving samples have also reported that caregivers use more psychotropic medications than non-caregiving controls[15,87,102]. Reports of somatic medication use

among caregivers are less consistent, but most studies do not demonstrate a significant difference in the use of these medications between caregiving and non-caregiving samples[42,87,103].

In summary, the findings for physical health effects of caregiving are more equivocal than those for mental health outcomes. Although a number of investigators report significant health effects among subsets of caregivers, patterns of findings across studies are not as consistent. Evidence linking caregiving to physical health indicators, such as reported illness, physical symptoms, healthcare utilization or health-related behaviors, is generally weak[15]. This may be due to different definitions of health, health outcome measures, caregiving and control samples (varying levels of vulnerability and resources), care recipient samples (functional vs. behavioral impairments) and the fact that some self-report measures of physical health may primarily reflect life satisfaction[104].

Evaluating links between caregiver distress and health outcomes will ultimately require complex, multivariate models that are tested prospectively, over an extended period of time. Despite methodological challenges inherent in the evaluation of caregiving outcomes, data from several laboratories lend weight to the argument that chronic stressors contribute to affective disorders and may alter caregivers' sympathetic, neuroendocrine and immunological function.

FAMILY CAREGIVING: RELOCATING THE CARE RECIPIENT

Placing a relative in a nursing home is a stressful event for both the family caregiver and the patient. Caregiving places substantial burdens upon the caregiver and these burdens increase with the progression of the disease. Yet demented persons are usually placed in nursing homes only when all other avenues have been tried and other resources are exhausted[105–107]. Generally, the decision is postponed long past the time when more objective persons see it as appropriate[108]. Or decisions may be crisis-driven, e.g. the care recipient wanders off, sets the stove on fire, or overdoses on pills. One reason this delay occurs is that some caregivers, especially spouses, believe that their role obliges them to sole caregiving responsibility and to never institutionalize their relative[109]. Others may have promised, "I'll never put you in a nursing home", or "... til death do us part". Children, while more likely than spouses to rely on formal services and less enduring than spouse caregivers, nevertheless delay placement decisions because of reluctance to reverse roles and take charge of a parent's life[110].

Overall, the literature indicates that the care recipient's extent of cognitive impairment, loss of self-care abilities, and disruptive behaviors; mediated by caregiver age, employment status, health, stress and burden, relationship with the care recipient, duration of caregiving, and support and moderation by caregiver minority status, kinship relationship with the care recipient, and use of in-home services and resources, are predictive of institutionalization. Cohen *et al.*[105] described seven variables that affect a caregiver's decision to institutionalize a dependent elder with dementia: use of services; enjoyment of caregiving; caregiver burden and health; caregiver rating; reaction to care receiver behavior and memory problems; and presence of troublesome behaviors. Six variables predicted actual institutionalization: caregiver health; caregiver burden; use of services; care receiver cognitive function; troublesome behaviors; and caregiver reaction to behaviors. Montgomery and Kosloski[110] compared predictors of placement for adult child caregivers and spouse caregivers. Higher income, eligibility for Medicaid, lower morale and age of the elder were associated with placement for both groups, but other predictors of placement were different. Notably, level of affection predicted placement for children, but not for spouses, while sense of obligation was predictive for spouses, but not for children, who were more likely to place the care recipient in a nursing home at all points in time. The probability of placement declined with time for a while, then leveled off, then rose as caregiving duration exceeded 30 months, with the probability increasing more sharply for child caregivers than for spouses.

Although the number of community services has increased to support family caregiving in the home, the extent to which these services are meeting the needs of caregivers is questioned[111–113]. Collins *et al.*[114] found that 40% of family caregivers who had placed their loved one with dementia in a nursing home, reported that the availability of at least one additional community service would have delayed the institutionalization. The assumptions that family members know how to provide all of the care that is needed and that they have access to the resources to assist them with provision of needed care in the home are not valid, according to current research[112]. As a result, studies by Archbold *et al.*[115], Brennan *et al.*[116] and Buckwalter *et al.*[117] have evaluated interventions to assist family caregivers in the home with skills, anticipation of decisions and role changes and access to resources.

The consideration of relocation raises the prospect of sharp role transition. For most spouses, relocation changes a longstanding pattern of living together and providing for the other. For children it can mean the restoration of a pattern in which the child is not living with, and/or is not directly responsible for, the care of the parent. Roles that were previously reversed from parent parenting child to child parenting parent are again reversed. Interviews conducted during the Family Involvement in Care research[118] revealed that adult child caregivers of persons with dementia found the decision to put parents in a nursing home very distressing. Frequently reported comments were: "... the worst time in my life"; "... it about killed me to do it"; "... it really bothered me because I knew she would be angry with me", or "... my brothers didn't agree with me and that was a worry". While spouses reported some of these feelings, they tended to be more concerned with the loss of spouse and of the role of caring for the mate. Comments included: "... I knew I would miss him"; "... I hated thinking about not being able to take care of him"; or "... I kept thinking about how he would probably miss me and the things I do for him".

Persons with dementia placed in nursing homes may be highly resistant and fearful of the change. Given their diminished capacity for reasoning, it can be impossible to convince them that they require institutionalization. This presents a very stressful dilemma for family caregivers. It may be more difficult for child caregivers than for spouses, because of the need to reverse roles. Constant requests to be taken home are especially stressful to families. On the other hand, spouses may find it more difficult if their long-term close relationship has been affectionate and loving. In Family Involvement in Care interviews[118], the majority of children, spouses and other relatives noted that it was very hard to actually place the relative in a nursing home. Comments were: "... I cried all the way home"; "... it was so empty at home and I felt so lonely"; "... I knew she would miss her things, so I took as much along as I could, pictures and such. She had so much and then so little, it didn't seem fair"; or "... he kept saying he wanted to go home and tried to leave with me ... it was so sad". Many of the same family members' comments, however, indicated that they also were relieved, but ambivalent: "... it was hard, but I felt like a weight had been lifted"; "... I feel guilty saying so, but I was so glad it was finally done"; "... I felt free to do some things for myself again"; or "... it was hard to do but I knew it was best for my family".

When caregivers lack the necessary skills to manage problematic behaviors effectively, care recipient behaviors often escalate, leading to increased levels of confusion and agitation[23,103] that have been cited as the primary reasons for institutionalizing a family member with dementia[46,119,120]. Considering the psychological and financial expense associated with placing a person with dementia in an institutional setting, interventions which help caregivers in the prevention and/or management of behavioral problems are both timely and significant. In support of this position, the 1993 *Report of the Advisory Panel on Alzheimer's Disease* recommends that emphasis be directed toward health services research that focuses on reducing the burdens of care for family members of persons with dementia.

Although our understanding of the dementias and the severe negative consequences of caregiving for this population has grown, too little research has focused on the development, implementation and evaluation of interventions, especially for family caregivers. The American Association for Geriatric Psychiatry, the Alzheimer's Association and the American Geriatrics Society, in consensus, state: "Interventions that reduce the risk of caregiver depression and improve tolerance and the capacity to care for patients in the home, including educational materials, counseling support groups, day care and respite care, are among the most promising areas for future research"[121].

CONCLUSION

Caring for a person with cognitive impairment is chronically stressful. For persons with dementia, caregiving can last an average of 15 years, with the task being a demanding and often overwhelming experience[62]. This chapter has summarized the research on family caregiving of persons with dementia in the community setting. Informal caregiving, mostly by family members, of elders with chronic illnesses and disabilities has increased during the past two decades due to growth in the proportion of elders in the population, shorter hospital stays, advancing technologies that forestall mortality, and continuing higher costs of health care, with limited reimbursement of caregiving by professionals in the home. As a result, the impact of informal caring on family members quickly became a concern of health professionals and social and behavioral researchers, especially in the context of dementia caregiving. After two decades of extensive attention by the public and researchers, there is some consensus that, while there are both negative and positive effects of informal caregiving, outcomes are different depending upon characteristics of the caregiver and the care recipient. Moreover, different interventions are effective in ameliorating negative caregiver outcomes for specific caregiver and care recipient contingencies.

The Sydney Dementia Carers' Training Program

Henry Brodaty

School of Psychiatry, University of New South Wales, Little Bay, Australia

In 1983, when we devised the Sydney Dementia Carers' Training Program, previously named the Prince Henry Hospital Dementia Caregivers' Training Program[1] and the Dementia Carers' Programme[2], we aspired to provide state-of-the-art caregiver intervention. Our aims were to reduce caregiver distress by addressing, where possible, all factors known to aggravate caregiver distress and to delay nursing home admission of persons with dementia.

A number of facts were already well known about caregivers. Caregivers had high levels of psychological morbidity and negative affect, and were more likely to be depressed and experience low morale. Caregivers most vulnerable to adverse psychological effects were women, spouses, care providers (rather than care managers) and those who were physically unwell, used immature coping mechanisms and were socially isolated. Lack of support from family and friends, critical comments from those

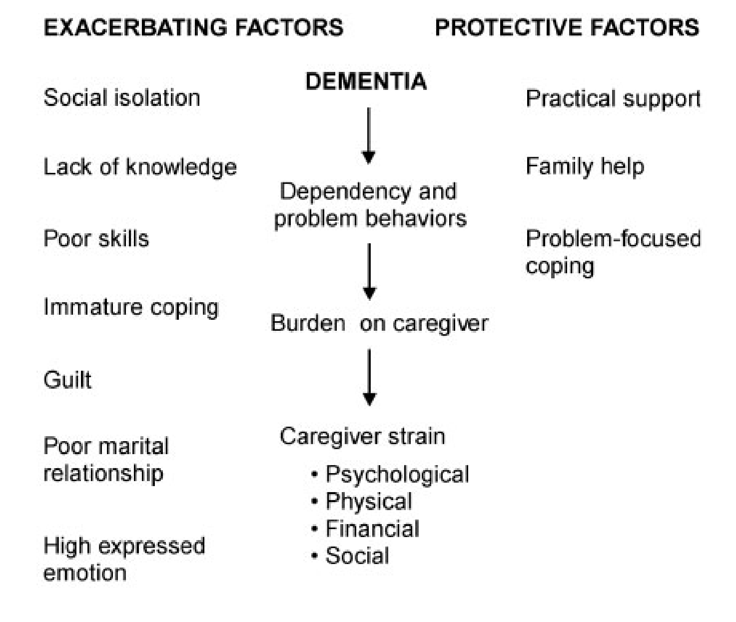

Figure 1 Model of the effects of dementia on caregivers

close to the caregiver and past history of psychological ill-health were other risk factors[3–6].

By the early 1980s, several intervention techniques had been described. These were designed to enhance the skills of caregivers in coping by cognitive-behavioural approaches, training in problem solving, educational therapy, meditative relaxation, training in social skills, supportive counselling of individuals or families, and the management of stress (see reviews[7,8]).

The outcomes of studies were limited by a number of methodological difficulties. The numbers of subjects were small, the period of follow-up was insufficient, the interventions were limited in scope, the baseline level of morbidity in subjects was often low, making it impossible to demonstrate improvement, and patient outcome was inadequately evaluated. Even so, there were some positive outcomes demonstrated: reduced family burden, decreased psychological morbidity, greater knowledge about dementia and more assertiveness and tolerance by caregivers[7].

A number of events, some unique, led to the development of the Sydney Dementia Carers' Training Program. First was the content, which was based on addressing factors known to exacerbate caregiver distress and indirectly potentiate nursing home admission. Second, there was a period of low occupancy on the psychiatric ward of a general hospital which, if not remedied, meant that some of the beds were under threat of closure. Third, the author, as the director and superintendent of that ward, was able to utilize a variety of staff to assist in the program. Fourth, a pilot program had proved feasible and anecdotally effective and facilitated a grant from the Australian Commonwealth Department of Health.

In the model underpinning the program (Figure 1), dementia leads to increasing dependency and a number of problem behaviours. These impose a burden on the caregiver, which can manifest as psychological, physical, financial and social strain. Exacerbating factors drive the reaction towards more psychological strain; protective factors ameliorate this.

CONTENT OF THE PROGRAM[a]

The content of the 10 day intensive residential program can be conceptualized under 10 rubrics [discipline of professional(s) conducting the session; number of sessions and duration of sessions are indicated in parentheses]:

1. *Reducing caregiver distress* (social worker/occupational therapist; 2×2 h + 1×1.5 h). These sessions were scheduled first, as we found that caregivers were unable to acquire new knowledge until their psychological distress had been dealt with. Sessions were informal, supportive and expressive in nature, with caregivers encouraged to unburden themselves. Discussion in the first session included topics such as caregivers' stories, the stresses of caring, associated feelings, setting limits for the person with dementia and caregiver, coping with caring, and role changes. The second session explored the additional themes of acceptance of the disease and how dementia affects relationships with family, friends and community. The third session focused on caregiver burn-out and how to look after one's individual needs.
2. *Combating isolation* (psychiatrist; 1×1 h). We aimed to reduce caregivers' social isolation by the group interaction, residential setting and bringing together four caregivers for 10 days. This often led to mini-support groups forming and was a rehearsal for participation in other support groups. After the intensive residential program, telephone conference calls and hospital follow-up visits strengthened the bonds between groups of four caregivers. Extended formal family sessions brought together an expanded network of potential caregivers. For many families it was the first time they had all gathered to discuss ways of assisting with care. Sometimes geographically distant families participated on speaker telephones.
3. *Guilt and separation*. Caregivers previously trapped by their role, guilt or their partner's insecurity or suspiciousness were separated from their charges for most sessions, and encouraged to enjoy a number of activities, such as excursions to the local shopping centre or coffee shop. This provided a rehearsal for more separateness when at home.
4. *New ways of thinking*
(a) *Assertiveness training* (psychologist or occupational therapist; 2×1.5 h). Participants were provided with a working knowledge of assertive, non-assertive and aggressive behaviours, with their own "Bill of Rights", and with strategies for coping with criticism. Sessions were concrete and used role-play extensively.
(b) *Re-roling* (psychologist; 1×2 h). This focused on roles—concept, definition (mainly by gender), expectations and responsibilities—and how these were affected by dementia. Many caregivers had considerable difficulty taking over roles relinquished by the dementing person, such as driving, organizing the family and dealing with bureaucracy. Required skills were identified and their development promoted.
(c) *Relaxation and stress management* (occupational therapist; 8×30 min, daily). Techniques for relaxation, meditation, use of physical imagery and progressive muscular relaxation, complemented by two half-hour discussions on the theory of relaxation and stress response, were very popular. Caregivers obtained audiotapes to practise techniques themselves and with their partners.

[a]Reproduced by permission from Brodaty *et al.*[1] Copyright John Wiley & Sons Ltd.

5. *New coping skills*
(a) *Communication* (psychologist; 1 × 2 h). The first half of this component was theoretical. It focused on:
- How to communicate with a dementing person.
- The functions and expectations of communication.
- How communication processes can be disrupted.
- Information on language impairment that occurs in dementia, such as receptive and expressive dysphasia.
- Techniques for clear communication, e.g. the four Ss—keep it simple, slow, short and specific[9].

In the second half, techniques were practised by each patient–caregiver dyad while being videotaped and/or observed by the group through a one-way mirror. Caregivers were able to review the videotape and analyse their performance and communication techniques.
(b) *Reality orientation* (occupational therapist; 1 × 1 h). This was based on a 24 h environmental reality orientation model with use of verbal techniques, signs, pictures, clocks, diaries and other strategies.
(c) *The therapeutic use of activities* (occupational therapist; 1 × 1 h). This introduced the concepts of activity as being goal-directed use of time, energy and attention. *Activity analysis* was explained as breaking tasks into small steps, then modifying, eliminating or replacing steps that prevented the dementing person from completing the task (e.g. having a bath, playing golf, cooking). There was also much discussion on appropriate leisure pursuits.
(d) *Reminiscence* (occupational therapist; 1 × 1 h). Caregivers were taught how to compile a "This Is Your Life" book, comprising mementos and photographs that described the past life of the patient. This proved to be a positive experience and subsequently provided a good stimulus for conversation and reminiscing.
(e) *Coping with physical frailty* (various; 3 × 1 h). First, a physiotherapist discussed back care, walking and mobility aids. Second, an occupational therapist discussed the use and abuse of aids to daily living; caregivers tried out many of these aids in a modified kitchen, bathroom and bedroom in the occupational therapy department. Third, a registered nurse outlined the care of bed-bound, chair-bound and incontinent persons.
6. *Fitness, diet, organizing the day and home* (various; 3 × 1 h).
(a) A physiotherapist encouraged fitness and flexibility in caregivers as well as patients. For example, a daily routine of walking after lunch was established.
(b) A dietitian outlined the principles of a healthy, balanced diet and discussed time-saving kitchen techniques as well as food fads and eating problems associated with dementia.
(c) In a session on *work simplification*, and *organization and safety in the home*, the occupational therapist explored techniques of how to prioritize and simplify tasks and how and when to recruit outside assistance. The aim was to help caregivers achieve a balance between work, leisure and rest in their lives. Safety issues pertinent to the older person and the dementing process were discussed and a safety checklist for the home and garden was provided.
7. *Medical aspects of dementia* (psychiatrist; 2 × 1 h). These sessions provided medical information on dementia and its different types, principles of management, psychiatric complications and behavioural changes, use and abuse of medication, the interaction of dementia and other illnesses, and prognosis. As with all of these sessions, much time was given to answering individual concerns.
8. *Using community services* (welfare officer; 1 × 1.5 h). This very practical session included procedures and eligibility for social securities, provision of useful contact persons, and access to and availability of services. For some caregivers it was a novelty to adopt the role of *care manager*, e.g. organizing other people, such as domiciliary nurses, to help with provision of care, rather than that of *care provider*, where the caregiver undertook tasks personally. Reinforcement was given that use of services did not represent failure or dereliction of duty. Numerous pamphlets were provided on domiciliary nursing care benefits, pensions, methods of assessing nursing homes and hostels and mechanisms for complaints about services.
9. *Planning for the future* (psychiatrist; 1 × 1 h). The last formal session was fairly open and considered *how to plan for emergencies*, e.g. should something happen to the caregiver. Other issues, such as driving, medications, safe use of alcohol, smoking, legal, medical and financial matters and other emergency contingencies were discussed.
10. *Coping with problem behaviours*. There was no time set to discuss these specifically, although each session was structured to allow discussion of current or potential problems, such as aggression or wandering. The aim was to give caregivers a broad education on the possible reasons for the emergence of problems and a repertoire of skills to prevent their occurrence or to deal with them if they occurred.

THE PATIENT PROGRAM

For caregivers to be able to learn in a relaxed setting, they needed to know that their partners were receiving satisfactory care. Patients had their own program, which consisted of: (a) general ward activities, such as occupational therapy, outings and relaxation classes; and (b) specific programs—group discussion of their frustrations with their memory loss, reminiscence therapy and a memory retraining program. Given a forum for honest and open discussion, patients established strong bonds with each other, were able to discuss their feelings surprisingly frankly and often became protective of each other. Memory techniques included use of visualization and one-tracking (focusing on one task to be remembered at a time). While we were unable to demonstrate any improvement in cognitive function[10], our impression was that patient morale improved.

Process

The course was residential and for a variety of (non-essential) reasons, as explained above, took place in the psychiatric ward of a general teaching hospital, with caregiver and patient couples sharing individual rooms. An advantage of this setting was the availability of facilities and staff. A disadvantage was the inappropriateness of some interactions with psychiatric patients, yet there was no attrition among the 96 participants who attended the program. The 10 day program began on a Tuesday and finished on the Thursday of the following week (Table 1). Our 5 day, Monday to Friday, pilot programs proved too congested and caregivers requested that a weekend be included. This allowed caregivers time to spend talking together, having fun, such as a picnic, and consolidating some of the knowledge previously presented.

A major aim of the course was for participants to enjoy themselves. Sadly, fun and spontaneity are often lacking from caregivers' lives. Leisure pursuits, such as walks, table games like "Trivial Pursuit", carpet bowls, singalongs, dances and going out for a drink, were included as part of the evening and weekend program. During these activities, caregivers would practise their

Table 1 Timetable of Dementia Caregivers' Training Program

	Morning	Afternoon	Evening
Day 1	Admission procedures Welcome and orientation	"Getting to know you" Reducing carer distress 1	Socializing
Day 2	Stress management and relaxation "Telling your story" Reducing carer distress 2	Healthy eating for older people	Film night
Day 3	Relaxation Re-roling	Reminiscence Keeping fit and healthy	Carer outing
Day 4	Relaxation Assertiveness training 1	Therapeutic use of activities and activity analysis Medical aspects of dementia 1	Socializing
Day 5	Relaxation practice with tape Picnic outing		Socializing
Day 6	Relaxation practice with tape Church	Sunday drive	Socializing
Day 7	Relaxation Communication	Assertiveness training 2 Medical aspects of dementia 2	Extended family sessions
Day 8	Stress management and relaxation Reality orientation	Work simplification and organization in the home Combating burnout	Extended family sessions
Day 9	Relaxation Use of community services	Coping with physical frailty	Socializing
Day 10	Relaxation "What if"—planning for the future	Farewell afternoon tea and presentation of diplomas	

skills of communication, activity analysis, reality orientation and reminiscence.

Patients and caregivers were given name tags and briefed daily after breakfast to review the previous night and to confirm each day's arrangements. Less threatening sessions were scheduled for the first week of the program; those that required more self-examination or were more confronting about the realities of the dementia were left until the second week. At the end of the program there was an afternoon tea graduation ceremony and presentation of a diploma.

Follow-through

Follow-through was an essential part of the program. While the 10 day program was both intensive and comprehensive and supplemented by take-home written materials and audiotapes, it was felt that the lessons would be lost without reinforcement. Telephone conferences were arranged with the coordinator at increasing time intervals over 12 months, starting at 2 weekly and finishing at 6 weekly intervals. The coordinator's input was gradually diminished on these telelinks. Towards the end of the year, the coordinator would absent herself from teleconference calls. Cohorts of caregivers attended the hospital for follow-up assessments at 3, 6 and 12 months after the completion of the program, thus providing opportunities for reunions. Relationships among cohorts of caregivers varied, with some establishing quite close friendships and continuing to meet informally at each other's houses. After the first year, annual telephone follow-ups were conducted. Two long-term outcomes were monitored, nursing home admission and death. Data on these endpoints were obtained for all patients.

THE TRIAL

We recruited subjects by seeking referrals from doctors, aged care and healthcare providers or by having articles in the media. While the pilot programs had been heavily subscribed, once the research proper began, the well-known "disappearing subjects" phenomenon was evident. Of the 96 caregivers who entered the study, 40 did so of their own initiative, 16 were referred by local doctors, 15 through the Alzheimer's Disease and Related Disorders Society, eight after media publicity, and 17 through other sources.

To be eligible, we required that patients be less than 80 years old (for follow-up purposes) and have mild to moderate dementia, defined by the *Diagnostic and Statistical Manual of Mental Disorders*, 3rd edn[11]. The patients had to live in a private home with a supporter, be able to understand English, not be a wanderer and not be aggressive. We stipulated that patients had to have dementia of mild to moderate severity defined as a score on the basic Activities of Daily Living of 0 or 1. All subjects agreed to random allocation to either a memory-retraining program (for patients only) or a dementia caregivers' program (as described above). Subjects were told that neither program offered a cure, but both offered the possibility of improvement in function. Institutional ethics committee approval was received prior to the trial and all subjects gave written informed consent.

Procedures

Prospective applicants for the program were sent questionnaires and the postal date on the envelope of the questionnaire determined which group eligible subjects were assigned to. Importantly, no systematic bias could have occurred because the time when caregivers sent their application was purely random and therefore meant that their allocation was not biased by any selection procedure. Subjects were assigned in turn to one of three treatment groups: *memory retraining program, immediate dementia caregivers' program*, or *wait-list or delayed dementia caregivers' program*. In the *memory retraining program*, patients were admitted for 10 days and received the patient component of the dementia caregivers' program, while

their caregivers had 10 days' respite. Those in the *delayed training group* received the dementia caregivers' program after approximately 6 months. We calculated a sample size of over 30 for each of the three groups as necessary for an intervention of moderate power (estimate 0.6) to produce a relevant effect size (estimate 0.67) for $\alpha = 0.5$.

Assessment

Patients were assessed on the Orientation Information Memory Concentration scale [OIMC, range 0–37 (37 = maximum cognitive functioning)[12]]; the Dementia Scale [range = 0–27 (higher score indicates worse function)[12]]; the Mini-Mental State Examination [range 0–30 (30 = maximum cognitive function, < 17 indicated important deterioration)[13]]; the 21 item Problem Behaviour Checklist[14] [range 0–42 (0 = no problems, 42 = all problems occurring frequently)]; the Activities of Daily Living [range 0–6 (0 = completely independent, 6 = completely dependent)[15]]; the Instrumental Activities of Daily Living [range 1–4 (1 = complete independence, higher scores indicate increasing dependence)[16]]; the 21 item Hamilton Rating Scale for Depression [range 0–64 (> 16 indicates important depression)[17]]; the Geriatric Depression Scale [range 0–20 (> 10 indicates possible depression)[18]]; and the Clinical Dementia Rating Scale for Dementia [range 0–3; (0 = healthy, 3 = severely demented)[19]].

Carers completed the General Health Questionnaire [range 0–30 (those with scores > 4 probably were considered to have significantly psychological morbidity)[20]]; and the Zung Depression Scale [range 20–80 (⩾ 40 indicated important depression)[21]] and were rated on the Hamilton Depression Rating Scale. They were asked to keep a health diary of all the healthcare visits made and medications taken by them and the patient over the 12 months of follow-up. They were also asked to keep a record of all visits to day centres and any days in residential care. Completion of the diaries was encouraged at the regular telephone conference sessions. Demographic data on all participants were collected and included the position on the Congalton scale for socioeconomic status [range 1–7 (1 = highest status occupation, 7 = lowest)[22]].

RESULTS

The Sample Defined

One hundred and one pairs of patients and caregivers entered the trial. Three of the 36 pairs in the *immediate carers' program* had insufficient follow-up data, and one of the 32 patients in the *memory retraining group* (MRP) changed caregivers during the follow-up period. These four pairs were excluded from further analyses. Two pairs in the *delayed carers' program* (DCP) completed intake and pretraining assessments but elected not to proceed with the training. Their data from the initial two assessments were included in the analyses at 0 and 6 months, but not subsequently. Otherwise all patients and caregivers who began the programs completed them.

This left 33 pairs in the immediate DCP, 32 in the wait-list DCP and 31 in the MRP. Of the 96 carers, 89 were spouses, four were siblings and three were children of patients. Forty-four caregivers were men and 30 of the 87 who completed the question affirmed their membership of the Alzheimer's Disease and Related Disorders Society. The caregivers' mean age was 67.7 (SD = 8.2 years).

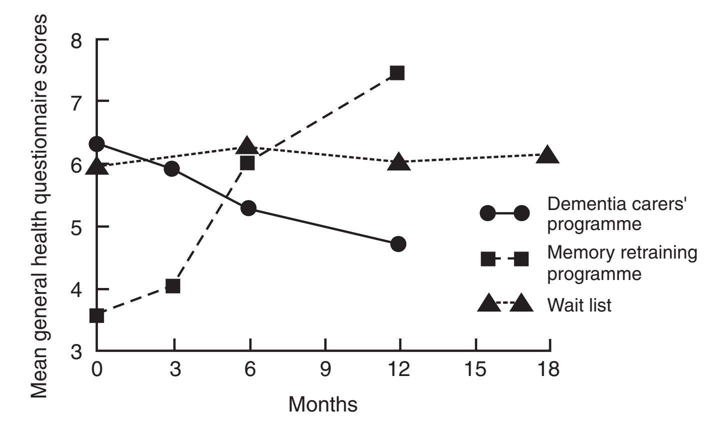

Figure 2 Mean General Health Questionnaire scores for carers in all three groups. Standard deviations of each group at zero, three, six, and twelve months respectively were 6.2, 5.8, 6.2, and 5.6 for the dementia carers' programme group; 6.3, 7.1, 8.4, and 9.4 for the memory retraining group; and 6.1, not available, 6.7, 6.6, and 7.7, at 18 months, for the wait list group. From Brodaty and Gresham[2], by permission of the BMJ Publishing Group

Of the 96 patients, 50 were men, 70 had probable Alzheimer's disease, 19 had multi-infarct dementia, and seven had other causes of dementia. Their average age was 70.2 (SD = 6.5 years; range 49–79 years) and they had had 10.4 (3.6) years' education and had mild-moderate dementia [Clinical Dementia Rating Scale score 1.1 (0.5)]. The duration of dementia, a mean of 3.8 (3.8) years, was similar in the three groups. The sample was predominantly middle-class ($n = 52$), with 16 from the upper socioeconomic classes and 25 from the lower socioeconomic classes. Data from three patients were missing. There were no significant differences between the three groups, for caregivers or patients, on any socioeconomic variable or initial measure of outcome at entry into the trial.

In later reports from the study, three subjects were excluded. One subject did not decline and he was subsequently rediagnosed as having benign forgetfulness; another subject who had undertaken the *memory retraining program* was excluded because he and his wife subsequently undertook a caregiver training program; and a third subject from the wait-list group did not provide sufficient data. Otherwise, all subjects declined over time, confirming their diagnosis of a progressive dementia. Diagnoses were able to be refined over time, so that of the 93 patients, 65 were subsequently diagnosed with probable Alzheimer's disease, 21 with multi-infarct dementia, three with Pick's disease and four with other uncertain cause of dementia (two subcortical dementia, one carbon monoxide poisoning and one diagnosis deferred). There were some slight differences in the baseline characteristics of patients and caregivers once these three pairs had been excluded, but these were trivial. Details can be found in the report from Brodaty *et al.*[1]

Caregivers' Outcome

Caregivers' psychological morbidity, as judged by the General Health Questionnaire (GHQ-30) declined significantly over 12 months in the immediate intervention but rose steadily in the memory retraining group. GHQ scores of those in the delayed training program remained steady (Figure 2). Scores on the Zung Depression Scale did not show this differential effect, probably reflecting the low initial scores on that scale and the biological nature of many of its items[21].

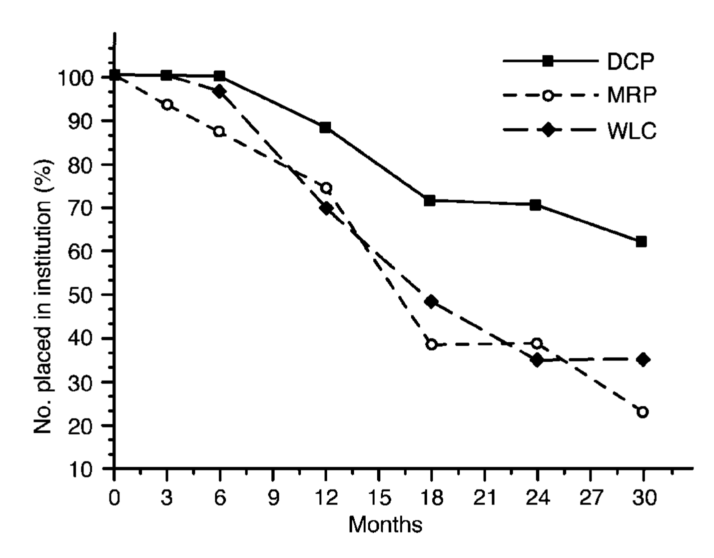

Figure 3 Survival curve showing percentage of patients not placed in an institution over time in the three programme groups. From Brodaty and Gresham[2], by permission of the BMJ Publishing Group

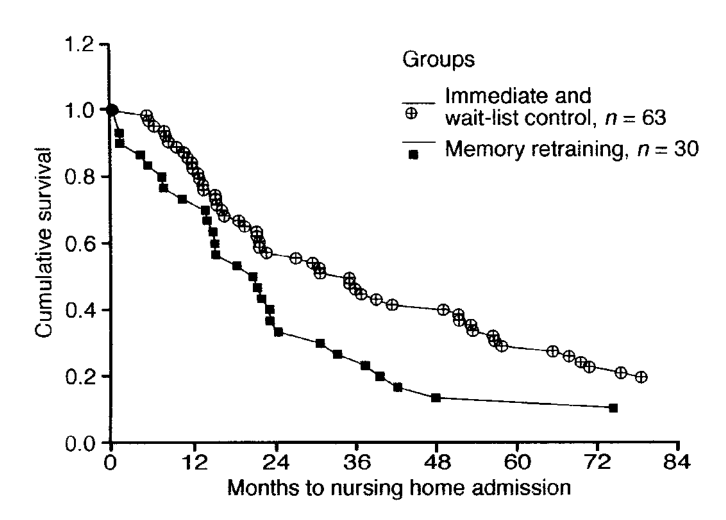

Figure 4 Kaplan–Meier survival functions for nursing home admission comparing the combined training groups with the memory retraining group. From Brodaty et al.[1], with permission. Copyright John Wiley & Sons Ltd

Patients' Outcomes

Over the 12 months there was a steady decline in all measures of patient cognition and function (Figure 2). Thus for the total sample, the MMSE scores declined from 17.1 (6.5) at baseline to 16.2 (7.3) at 6 months and 15.2 (7.6) at 12 months. Similarly, the Blessed dementia scale score increased from 7.0 (2.9) to 8.2 (4.3) and 10.4 (5.4) over the 12 months. Activities of Daily Living declined from 0.3 (0.6) to 1.1 (1.4) and 1.7 (1.7) over the 12 months. There were no differences between the three groups in the rate of patient decline. Patients were not depressed clinically. Fewer than six at any assessment over the 12 months had a Hamilton score of $\geqslant 16$. Their mean Hamilton and Geriatric Depression scale scores remained low and stable over time.

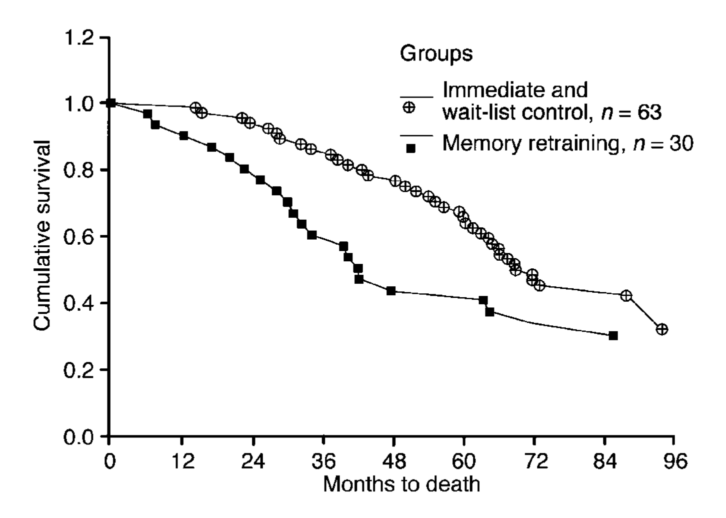

Figure 5 Kaplan–Meier survival functions for death comparing the combined training groups with the memory retraining group. From Brodaty et al.[1], with permission. Copyright John Wiley & Sons Ltd

Nursing Home Admission and Mortality

In the first 30 months, there was a marked difference between the groups in the percentage of patients still at home (Lee-Desu statistic = 6.19, df = 2, $p < 0.05$) (Figure 3). At 8 years follow-up, the rates of nursing home admission in the immediate and delayed carer training groups were similar and were combined, allowing for a comparison of the effect of caregiver training in general to the memory retraining group (Figure 4). Using Kaplan–Meier survival functions, there was a significant difference between the groups in survival at home and mortality. The rates of death of patients at 30 month and 8 year reviews were lower where caregivers had had training (Figure 5).

Costs

Program Costs and Institutional Costs

As the program was conducted within the psychiatric unit of a general teaching hospital, it was more expensive than may have been necessary. Even so, we were able to demonstrate that the costs of training were more than counterbalanced by the delay in nursing home admission. By 39 months follow-up, there were only 32 patients still alive at home: 17 of 31 (55%) from the immediate carers' program, 11 of 29 (38%) from the delayed carers' program and 4 of 30 (13%) from the memory retraining program. At the time, the average cost of a nursing home bed was *$92.23/day. We calculated the total institutional costs for the three groups as $19 918 for immediate carers' training patients, $27 375 for delayed carers' program patients, and $36 753 for memory retraining program patients. The cost of the training was estimated in 1991 as $8868, including the hospital stay and 12 months' follow-up. This represented a saving of $7967 (Australian) ($5975 US) per couple in the immediate training program (compared to those in the memory training program) in the first 39 months of the program.

*Costs quoted in Australian dollars throughout. $1 Australian = $0.75 US at that time.

Health Care and Lost Employment Costs

We found that over the first 12 months of follow-up there were no appreciable differences between the groups in the number of visits to all doctors, general practitioners or non-medical health practitioners; or in the use of medication or of hospitals. In the second 6 months of the first year, memory retraining patients spent more nights in institutional care than the other two groups.

Prediction of Nursing Home Admission and Death

By 5 years follow-up, 75.8% of patients had entered a nursing home and 41.8% had died. Dementia severity and rate of deterioration and carer psychological morbidity significantly influenced rates of nursing home admission and death. These rates were comparable to previous reports[23,24].

Carer training had a significant protective effect against nursing home admission and, surprisingly (and independently of nursing home admission), against death. There was an association between earlier nursing home admission and caregiver distress, as measured by the GHQ; index measures of dementia severity and problem behaviours; more rapid decline in cognitive function; more rapid decline in overall dementia severity; and increase in problem behaviours.

COMMENTS

Carer intervention programs have considerable potential. They can improve the quality of life of the carers and probably that of patients[1]. We have recently reviewed 35 controlled studies of carer intervention and found that a minority of them demonstrated clinically significant beneficial effects[8].

Limitations to previous studies included: heterogeneity of patients and of carers in the sample; variety of recruitment methods; ceiling and floor effects as regards the outcome measures; low number of numbers and insufficient power; lack of blindness; insufficient duration of follow-up; and lack of specificity in matching interventions with carer needs[8].

The Sydney Carer Training Program study overcame many of these limitations and demonstrated psychological improvement in carers, delay in nursing home admissions and cost savings. The delay in institutionalization was not at the expense of increased carer distress.

There were a number of unanswered questions from the study. It was not possible to know which components of the package of interventions were effective. We provided a broad-spectrum intervention—something for everybody. This was confirmed at exit interviews after 12 months' follow-up, where each component of the program was identified by at least one carer as being helpful to him/her.

The program was unnecessarily expensive in that it was conducted within a hospital setting. While this provided many advantages, it was very costly, and the cost analyses allowed for 20 hospital bed-days per patient–carer couple. We do not know whether the program needed to be residential, although this did provide some advantages. The advantages of residential programs are that they promote more cohesive bonding and allow for observation of behaviours not easily accessible within a day program. Clearly, residential programs could be conducted in less expensive settings.

The ideal number of couples per training cohort is unknown, but our impression was that numbers greater than 10 would impede the group process. Also, our experience suggested that the earlier the intervention, the better, and that matching carer cohorts, e.g. spouses, younger people with dementia, socioeconomically and geographically, may have advantages.

Future research might benefit from a more targeted, selective approach—matching the needs of carers with appropriate interventions. The questions of which carer interventions benefit which carers for which patients at what time in the course of the dementia are complex. Finally, the advent of specific drug treatments for Alzheimer's disease begs the question of whether carer interventions plus drug treatments are superior to either alone.

Elder Abuse— Epidemiology, Recognition and Management

Martin J. Vernon
South Manchester University Hospitals NHS Trust, Manchester, UK

During the 1980s, elder abuse emerged as a health and social issue of international importance[1]. It is defined as "a single or repeated act or lack of appropriate action occurring within any relationship where there is an expectation of trust which causes harm or distress to an older person"[2]. While most authorities include self-neglect within the broad definition, acts which threaten an elder's well-being as a consequence of their competently made decisions are specifically excluded.

Abuse may occur in one of two settings. Domestic abuse is perpetrated within the home of the victim or a caregiver by either a relative or other care provider. Institutional abuse occurs within a designated care facility (residential or nursing home or hospital), perpetrated by one or more individuals having an obligation to care for and protect the victim.

Five major categories of abuse have been identified[3,4]:

1. *Physical*: any activity involving force to generate bodily injury or pain, including striking or burning and the use of physical or pharmacological restraint.
2. *Sexual*: any form of non-consensual sexual contact, including unwanted touching, rape, sodomy and coerced nudity.
3. *Psychological*: the infliction of distress through verbal or non-verbal acts, including insults, threats, humiliation, infantilization and harrassment.
4. *Financial*: the improper use of an elder's property or assets, including theft, deception, coercion and misuse of authority to act, such as power of attorney.
5. *Neglect*: the refusal or failure to fulfil care obligations, including the provision of food, water, clothing, medication, comfort and protection.

PREVALENCE AND INCIDENCE

Variability in case definition obscures direct comparison, although the prevalence of elder abuse is broadly similar throughout Europe and North America. To date there are few data from developing countries (Table 138c.1). With the exception of the USA, a lack of national incidence data reflects widespread absence of formal mechanisms for case reporting and validation. American data estimate the incidence of domestic abuse at 450 000 elderly people/year, of which only 16% are reported to statutory agencies[5].

VICTIM CHARACTERISTICS

Likelihood of being abused increases with age[6]. Elders aged over 85 are at particular risk of neglect[7], financial abuse[8] and abuse by designated carers[9]. There is some evidence that minority ethnicity and non-White race represent risk factors for abuse[6,10]. Women are more likely than men to be victims[11] but this observation may be confounded by greater likelihood of living alone, which is associated with financial abuse[8]. In contrast, victims of physical, sexual or psychological abuse are likely to live with others, particularly a spouse or child[12]. Poverty elevates the risk of abuse[6].

The role of cognitive impairment is complex. Factors predicting abuse of dementia patients include behavioural disturbance, poor premorbid relationship with a carer and psychological or physical abuse by the patient[13]. The severity of cognitive impairment does not appear to be associated with abuse. Spouses caring for dementia patients are at particular risk of psychological and physical abuse[35]. In one series, one-third of carers reported physical abuse by the patient, which in turn was associated with abuse of the patient by the carer[14].

Vulnerability to abuse has been associated with certain personality traits[15]. Victims of psychological abuse have less ability to control problem situations and tend to react aggressively when feeling anger or frustration. In contrast, physical abuse victims pursue passive or avoidant behaviour, while financial abuse victims possess negative beliefs of self-efficacy and turn aggression or frustration on themselves.

ABUSER CHARACTERISTICS

Greater understanding of abusive situations has focused attention on those perpetrating abuse. Carers who suffer social isolation, feel unsupported and are financially dependent are at risk of abusing[13,16,17]. Men are more likely to abuse than women, and more likely to cause physical abuse[18]. Psychological abuse is more likely to be caused by women. Abusers tend to suffer declining health and mental illness increases the risk of perpetrating abuse[19]. In particular, depression and anxiety among carers are associated with abusive behaviour[20,21].

The role of drug and alcohol misuse is controversial. Abusers identified as misusing substances are likely to be male children of the victim, less likely to provide care and more likely to cause physical or psychological abuse than financial abuse[22]. However, in one study of referrals to a community psychiatric service, consumption of alcohol by the carer was not associated with abuse[13].

Table 138c.1 Prevalence (%) of elder abuse (aged 65+)

Abuse type	UK[1]	The Netherlands[2]	USA[3]	Canada[4]	Sri Lanka[5]*
Physical	1.5	1.2	2.0	0.5	1.5
Psychological	5.4	3.2	1.1	1.4	1.5
Financial	1.5	1.4	–	2.5	1.0

Table 138c.2 Risk factors for abuse

Victim
- Age >75
- Living alone (financial abuse)
- Living with spouse or child (physical, sexual or psychological abuse)
- Low income
- Cognitive impairment
- Poor pre-morbid relationship with carer
- Abusive, passive or avoidant behaviour

Abuser
- Male (physical abuse)
- Female (psychological abuse)
- Social isolation
- Financial dependency
- Impaired physical or mental health
- Substance abuse
- History of receiving or perpetrating abuse

NATURAL HISTORY OF ABUSE

Those who have suffered abuse are themselves likely to become abusers[23] and carers who have violent elders express more violence to their dependants[24]. In one follow-up study, 20% of victims suffered physical or financial damage following abuse, although 70% were able to stop abuse either themselves or with the help of others[31]. Corroborated abuse is associated with greater risk of death for elderly victims (odds ratio 3.1; 95% CI, 1.4–6.7) after adjusting for co-morbid and demographic factors[25]. However, abuse rarely leads to homicide: in one study only 2% of elderly homicides could be attributed to abuse[26].

RECOGNITION

Diagnosis of elder abuse requires a high index of suspicion. Professionals should be alert to the presence of one or more risk factors for abuse (Table 138c.2) and sensitive to principal abuse signals (Table 138c.3). In cases of suspected abuse, a coordinated multi-agency approach must identify all care needs and deficiencies. Corroborated history must be obtained from all participants, including victim, alleged abuser and designated carers, with careful verification of information obtained from cognitively impaired individuals.

Symptoms and signs of abuse must be elicited during a comprehensive clinical assessment to which the victim consents (Table 138c.4). Accurate documentation, including note keeping, radiology and photography, will facilitate future management planning. The presence or absence of particular features do not alone confirm or exclude the diagnosis of abuse. Nevertheless, defensiveness and irritability by caregivers are predictive of abuse, poor physical care predicts physical abuse and psychosocial stress or exploitation predict psychological abuse[27].

Table 138c.3 Abuse signals[29]

- Caregiver personal problems
- Caregiver interpersonal problems
- Care receiver social support shortage and history of abuse

Table 138c.4 Symptoms and signs of abuse[4]

Physical abuse
- Carer refusal to permit examination
- Reports of being hit, kicked or mistreated
- Unexplained behavioural disturbance
- Presence of unexplained bruises, lacerations, ligature marks, fractures
- Untreated injuries in various stages of healing
- Inappropriate use of prescribed medication

Sexual abuse
- Reports of sexual assault or rape
- Bruising of breasts or genital area
- Torn, stained or bloody underclothing
- Unexplained genital infection or bleeding

Psychological abuse
- Reports of verbal or emotional mistreatment
- Withdrawal, non-communication or non-responsiveness
- Unexplained or unusual agitation or behavioural disturbance

Financial abuse
- Reports of financial exploitation
- Unauthorized or unexplained changes in banking practice
- Abrupt, unauthorized or unexplained changes to financial documentation
- Unexplained disappearance of assets
- Unmet care needs in the presence of adequate financial resources
- Sudden appearance of individuals asserting their rights to an elder's assets

Neglect
- Reports of mistreatment
- Failure to provide food and hydration
- Failure to meet clearly identified care needs
- Hazardous or unsanitary living conditions

MANAGEMENT

Denial, resistance to intervention, ignorance of intervention protocols, confidentiality and fear of reprisal have all been cited as professional barriers to the management of elder abuse[28]. Central to effective management is the establishment of a single coordinating agency, providing education, advice and access to resources. Intervention models should be low-cost, multidisciplinary, collaborative and capable of evaluating outcomes[29]. The key elements of such a model may include:

- Educational resources.
- Mechanisms for accurate case identification.
- Professionals to identify and deal with health, social, financial and legal issues.
- Workers to support and monitor victims and their care networks.
- Victim empowerment and advocacy groups.

Identification of incipient abuse should generate a brisk response to avoid escalation. Management must aim to preserve

autonomous choice for the victim and avoid paternalistic action that seeks to provide a speedy resolution, perhaps through institutionalization. Accurate identification of unmet care needs should generate planned and effective care strategies, which engender safety without intrusion. Given that abuse may be multidirectional, attention may need to be focused on both victim and abuser.

While overtly criminal activity, such as theft or assault, may be dealt with by prevailing criminal law, most countries have eschewed a legislative approach to elder abuse, relying instead upon health and social service agencies to develop locally applicable policies and procedures. In the USA mandatory reporting laws have achieved only limited success and professionals remain unfamiliar with reporting procedures[30]. Of greater potential benefit for the future is the emergence of national organizations, aiming to prevent the abuse of older people by disseminating research, informing public policy and providing specialist advice to both professionals and the general public[3].

The Care of the Dying Patient

Robert E. Nelson and Keith G. Meador
Duke Institute on Care at the End of Life, Durham, NC, USA

The care of the older dying patient is provided in many settings, including homes, tertiary care hospitals, nursing care facilities and inpatient hospices. The issues relevant to psychiatry are relatively consistent across these contexts. This chapter provides an overview of the major psychiatric syndromes and therapies that are covered more thoroughly in the primary palliative care literature.

PSYCHIATRIC SYNDROMES IN PALLIATIVE CARE

Depression

Depression is common in terminal illness. The prevalence of a major depressive syndrome in late-stage cancer patients has been estimated at 23–58%, varying by diagnostic criteria and methodology[1]. The diagnosis of depression is sometimes difficult to make in the setting of medical illness, because many of the symptoms of the patient's condition may overlap with those of depression, such as fatigue, loss of energy and altered sleep and appetite. Furthermore, many of these same symptoms can be side effects of medications, such as corticosteroids or chemotherapeutic agents. The general approach to this diagnostic problem is to rely more on the psychological and cognitive symptoms of depression, such as worthlessness, hopelessness, excessive guilt and suicidal ideation[2]. One method used to clarify the distinction between depression and medical illness is the substitution of physical symptoms of uncertain etiology with psychological counterparts. An example of this approach is found in the Endicott Substitution Criteria[3], which replaces physical symptoms as follows: (a) change in appetite and weight is replaced by tearfulness and depressed appearance; (b) sleep disturbance is exchanged for social withdrawal and decreased talkativeness; (c) fatigue and loss of energy are substituted with brooding, self-pity and pessimism; and (d) diminished concentration and indecisiveness are replaced by lack of reactivity.

Another complexity in diagnosing depression in dying older adults is the question of how much of a patient's symptoms should be attributed to the normal difficulties of adjusting to the terminal nature of his/her diagnosis. When interviewing the patient, each of the clinical symptoms of depression should be explored in detail, with special attention to its pervasiveness and its interference in functioning. For example, hopelessness may be understandable with regards to hoping for a cure or recovery, but patients who are not depressed may be able to maintain hope for other improvements, such as better symptom control, or a better connection with their loved ones before their death. Hopelessness that is accompanied by despair or suicidal ideation is highly associated with a depressive syndrome and usually merits treatment[4]. While the multitude of issues relevant to its discussion is beyond the scope of this chapter, the assisted suicide movement heightens the need for careful assessment of depressive symptoms in the elderly dying patient.

The treatment of depression in terminally ill older patients often includes pharmacotherapy and is similar to other geriatric settings in its attention to managing symptoms and side effects. For this reason, selective serotonin reuptake inhibitors (SSRIs) are widely used in this setting because of their tolerability and their ability to also address anxiety. However, the principal side effect of SSRIs, gastrointestinal upset, can lead to weight loss, which is particularly detrimental to debilitated, medically fragile patients. Special care needs to be taken regarding drug interactions of the cytochrome P450 system with this class of drugs. Venlafaxine, a serotonin–norepinephrine reuptake inhibitor (SNRI), is less likely to interact with other medications because of its low protein binding (35%). Terminal illness makes a second variable relevant in medication choice, that of likely duration of treatment. In the setting of a life expectancy of days to weeks, an SSRI will not have time to take effect. For this reason, many clinicians favor the shorter-acting SSRIs, such as sertraline or citalopram. Bupropion has a similarly low side-effect profile as the SSRIs and also has some of the same dopamine agonist properties as the psychostimulants (see below), which may make it a good alternative in this setting. Tricyclic antidepressants are useful as adjuvant pain control and for sleep, but their side-effect profile and drug interactions make them a second-line choice.

Psychostimulants are a well-studied alternative for treating depression in terminally ill patients. While they are less useful in general populations because of tolerance and abuse potential, patients at the end of life can tolerate stimulants for up to a year without significant abuse problems[2]. Particularly helpful in the depressed patient with psychomotor retardation and mild cognitive impairment, stimulants such as methylphenidate and dextroamphetamine have been shown to reduce sedation from narcotic analgesics and also have adjuvant analgesic effects in cancer patients[5]. Pemoline is a less potent stimulant with a lower abuse potential than methylphenidate, and therefore has the advantage of being less regulated by the federal government. Also, it is available in a chewable form that can be advantageous for patients who have trouble swallowing or have intestinal obstruction[6].

Anxiety

As with depression, anxiety must be viewed as part of a normal spectrum in the patient's reaction to a life-shortening illness. Death can be seen as a model for human feelings of abandonment

and separation[7] and therefore brings with it the likelihood of anxiety that needs to be addressed. Such anxiety can often interfere with interpersonal relationships and impair the patient's ability to understand and make decisions about his/her treatment. The range of etiologies for anxiety in the terminally ill is wide, and includes the full range of psychiatric disorders (adjustment disorder, panic, generalized anxiety disorder, phobia) but also covers a number of medical conditions such as hypoxia, sepsis, pain, akathisia, and withdrawal from alcohol, barbiturates or benzodiazepines[8]. One must also consider the restlessness and agitation that can be part of delirium. Each patient's anxiety must be assessed with empathy and a special care toward building rapport with the patient, since open discussion in itself can be very therapeutic in the patient who fears abandonment at the end of life.

When a patient's level of distress is sufficiently intense, treatment is warranted. In mild cases, cognitive–behavioral techniques, such as progressive muscle relaxation, can be very effective[9]. With more serious anxiety in terminally ill patients, pharmacotherapy is indicated. Benzodiazepines are a mainstay of anxiolytic treatment in the population, especially because of the decreased concern regarding abuse potential. Short-acting agents, such as lorazepam and alprazolam, are favored for older adults over their longer-acting counterparts, such as diazepam and clonazepam, because of the potential for the impaired metabolism in many elderly individuals to lead to toxic accumulation of drugs or their metabolites. Several of these medications are available parenterally, as is a rectal form of diazepam, which is widely used in the hospice setting. Neuroleptics, such as haloperidol and risperidone, tend to be favored when the etiology of anxiety is suspected to be due to corticosteroids or delirium, or if there are psychotic symptoms associated with the anxiety[2]. Hydroxyzine is an antihistamine which is an effective sedative, anxiolytic and also has some analgesic properties and has minimal side effects[10,11]. Lastly, opiates are very effective in reducing anxiety, especially when it is associated with pain. Their use, however, is limited by respiratory depression.

Delirium

Delirium is a disorder of arousal and cognition caused by a medical condition that has relatively rapid onset and fluctuating course. Delirium has a prevalence of one-quarter to one-half of patients at the end of life[12]. This condition greatly complicates the treatment of the patient's other symptoms, such as pain, and causes great concern in family members and staff. In many cases delirium is reversible, even in relatively advanced terminal illness. Therefore, an investigation into reversible causes of delirium should be considered, including complete blood count, electrolyte studies, including calcium level and coagulation panel to rule out sepsis, dehydration, hypercalcemia and disseminated intravascular coagulation.

The diagnostic work-up of delirium in the terminally ill differs from that of the general population, in that special consideration must be made regarding the patient's or the family's wishes for invasive procedures to diagnose or treat the underlying cause of the delirium. The cause of terminal delirium most often is multifactorial or may not be found. Furthermore, when a distinct cause is found, it may be irreversible (such as hepatic failure or brain metastasis)[2]. In one study, an etiology was discovered in less than 50% of terminally ill patients with delirium[13]. Lastly, it should be noted that in the last 24–48 h before death, cognitive changes are usually irreversible and are attributable to multiple organ failure.

Treatment of delirium involves correction of any reversible underlying causes that can be found; supportive therapies, such as fluid, nutrition and vitamins are often helpful. Non-pharmacologic interventions to help reduce anxiety and disorientation include a quiet, well-lit room with familiar objects, a visible clock or calendar and the presence of family[12]. When these measures are insufficient, neuroleptics are the treatment of choice, especially in patients with an agitated presentation. Haloperidol in low doses is still favored by many clinicians; intravenous administration can hasten the onset of action, and may be less apt to cause extrapyramidal side effects than the oral form. If sedation is necessary, a short-acting benzodiazepine can be added.

PSYCHOSOCIAL INTERVENTIONS IN PALLIATIVE CARE

Even in the absence of serious psychiatric morbidity, the end of life can be a period of considerable intrapsychic and interpersonal conflict for the patient. In many cases, psychotherapeutic interventions can offer considerable benefits to a palliative care setting. The fact that this area of intervention is not better studied may reflect anxieties in therapists who are forced to confront their own mortality in providing palliative care[14]. Methods vary in the treatment of dying patients, but some common elements unite the different approaches. In general, psychotherapy with patients with terminal illness should seek to:

1. *Allow the patient to openly communicate his/her feelings about death*. The dying patient experiences many fears, and often feels isolated because there is no-one with whom they can be shared[15].
2. *Strengthen the interpersonal bonds with those who will survive the patient*. This serves to alleviate the sense of abandonment that accompanies dying and allows the patient a sense of having "put affairs in order". It is also important for the survivors and their eventual grieving process, since ambivalent feelings toward the deceased are a risk factor for complicated bereavement[16].
3. *Establish hope while gently confronting denial*. While hope of cure may not be realistic, it can be replaced by the hope to live to be present at certain near-term events such as a graduation. Similarly, patients can hope for dignity in their final days, for freedom from pain or for their personal understanding of an afterlife.
4. *Help the patient find existential meaning and coherence in his life and in his death.*

Kubler-Ross

Any discussion of the psychology of dying owes a debt to Ellen Kubler-Ross and her seminal book, *On Death and Dying*[17]. Kubler-Ross interviewed hundreds of patients with terminal illness and described the process of dying in five stages: (a) *denial and isolation*, in which the patient refuses to believe he/she is terminally ill and feels suddenly alienated from the rest of the population that is not acutely dying; (b) *anger*, which can be expressed either overtly or in subtle, passive ways, depending on the personality of the individual; (c) *bargaining*, in which the patient seeks to prolong life by making promises to a higher power; (d) *depression*, the sense of existential loss upon realizing that death is unavoidable; (e) *acceptance*, in which the patient achieves a serenity and grace even in the face of death and comes to terms with the inevitable. Kubler-Ross herself states that these stages may recur several times and vary in order throughout the patient's terminal illness, and any one stage may be missing altogether. Therefore, these stages should only serve as guideposts to anchor one's clinical assessment and interpretation of the dying

patient. Any attempt by the therapist to impose the stages as a structure can be an undue burden placed on the dying.

Psychotherapeutic Care

Psychotherapeutic approaches vary widely but, in general, the psychodynamic modes employ open-ended methods through which the patient gains insight. Underlying this approach is the belief that by better understanding the emotional pain of terminal illness, the patient will gain some relief from it[15]. The therapist pays careful attention to the patient's defenses, such as denial, displacement, counterdependency and dependency, and those that are felt to be adaptive are gently reinforced. If the defense is maladaptive, the question becomes whether the patient could tolerate an attempt to change it. Denial is felt to be the most common defense encountered in clinical practice, and it can be the most difficult to navigate for those who do not commonly work with the dying. The decision of whether or not to confront denial plagues psychiatrists, primary physicians and families alike. Stedeford[15] recommends that denial is a problem only when it is the sole or prominent defense. It then blocks communication with family and friends and prevents making suitable plans for the future. Often denial serves an important role in allowing the patient time to assimilate gradually information that would be overwhelming if absorbed all at once. Connor[18] believes that most denial is used to preserve interpersonal relationships. In this model, patients use denial primarily to cope with guilt about the effect of their condition on others, to protect others from the emotional stress they might feel if the patient were to openly acknowledge his/her condition and feelings, or out of fear of abandonment. He devised an intervention for this type of denial through a structured set of questions displayed in Table 138d.1.

Some other techniques are especially appropriate with dying older patients. Problem-solving therapy is a brief treatment that attempts to alleviate emotional symptoms by focusing on the social and practical difficulties faced by patients[19]. These problems are linked to the patient's symptoms, and the patient is helped to solve the problem by breaking it down into stages as follows: (a) clarification and definition of the problem; (b) setting of achievable goals; (c) consideration of alternative solutions; (d) selection of a preferred solution; (e) clarification of the necessary steps to implement the solution; (f) evaluation of progress. The advantages of this therapy are its brief format, which is sometimes necessary to fit the time frame of dying patients, as well as its accessibility to patients, who are sometimes uncomfortable with the jargon of psychotherapy. Cognitive and behavioral techniques are widely used to address specific symptoms, such as anxiety and phobias, through progressive muscle relaxation, imagery exercises or cognitive restructuring[9]. Guided imagery and trance states have also been successfully used to treat cancer pain. Education is often overlooked as a highly therapeutic tool to combat anxiety, since much of a dying patient's fear is generated by the unknown. The resources to assist in this education of the patient and family are growing exponentially and are available through varied media.

Table 138d.1 Structured psychosocial intervention for denial

1. Different people experience different kinds of difficulties when they are ill. What, for you, have been some of the most difficult aspects of having your illness?
2. Are there any things you do, or that other people do, that make these difficulties easier to deal with?
3. Is there anything you or other people do, that make these difficulties harder to deal with?
4. Do you believe you will or will not recover from this illness?
5. Have you had any close encounters with death?
6. What effect has your illness had on your family and close friends, and how have they reacted to it?
7. How do you feel about the way in which your family and friends have been affected by or have reacted to your illness?
8. Is there anything good that has come out of your having your illness?
9. Are there any other thoughts or feelings about your illness or the questions I've asked that you'd like to talk more about?

From Connor[18], with permission.

Psychological Benefits of Hospice Care

The first modern hospice was founded in 1967 in England to address concerns about the poor training of physicians to deal with terminal illness. Since then, the hospice movement has grown and spread to the USA, where roughly 20% of all deaths are now accounted for by patients who use hospices. The hospice approach seeks to improve the quality of the end of life by focusing on the whole patient, including his/her medical, pain relief, emotional and spiritual needs. Hospices employ a number of the above described therapeutic interventions through varied disciplines with a distinctive commitment to a team-based approach. Along with the psychological benefits for the dying patient in receiving this interdisciplinary, psychologically sensitive care at the end of life, there appears to be a psychological benefit to survivors of patients who use hospices; McNeilly and Hillary found survivors of hospice patients less likely to regret not having more openly expressed feelings to the person they cared for than those who used a home health care group[20]. Hospices can be seen as an intentional aid to the patient in his/her psychological journey at the end of life in its explicit commitment to helping the patient "die well", as he/she understands and interprets it, while maintaining an abiding commitment to the family and other survivors.

Although psychiatric care of the dying older patient embodies many challenges, it is full of rewards for the physician, patient and the patient's families. The reciprocity inherent within the relationship with dying patients is profound in its implications for educating us about life, suffering and adaptation. The more capable we become of caring well for the dying during this transition in their lives, the better we will be at understanding and caring for all of our patients.

Prevention in Mental Disorders of Late Life

Barry D. Lebowitz and Jane L. Pearson
National Institute of Mental Health, Bethesda, MD, USA

INTRODUCTION

In its influential 1994 report, *Reducing Risks for Mental Disorders: Frontiers for Preventive Intervention Research*, the Institute of Medicine (IoM) of the US National Academy of Sciences[1] assessed the state of knowledge in prevention research and identified directions for future scientific development. The index of this substantial volume contains no entries for "aging", "aged", "elderly", "geriatric" or "gerontological". In a section on illustrative preventive intervention research programs, examples are given of two service programs, one for caregivers of patients with Alzheimer's disease and one for widows, that are considered to have relevance to prevention. The authors could identify no randomized controlled preventive trials in the area of aging.

Prevention in the mental health field has been seen, traditionally, as an area that has been implicitly restricted to those concerns designed for application to issues in childhood and adolescence. If anything, prevention in geriatrics was seen as an oxymoron. Very simply, prevention was taken to mean youth. Theory and research in prevention were restricted to issues of child development and intervention early in the life course.

Why be concerned with prevention in late life? As is well covered in other sections of this text, there is the demographic imperative brought about by the overall aging of the world population and, in particular, by the aging of the older population. As pointed out in the classic papers by Gruenberg[2] and Kramer[3], the same dynamics—public health measures, technological development and lifestyle changes—that created this growth in the overall population were also relevant to growth of the population of those with chronic illnesses and disabilities. They conclude that, in the absence of cures or effective preventive strategies, we will see an explosion in the number of older persons with serious and persistent disabling illnesses, particularly mental disorders. The availability of more efficacious treatments and the accessibility of appropriate services in the community combined to produce huge gains in the life expectancy of those with mental disorders who, in earlier times, would have died long before reaching old age. This demographic imperative leads to the conclusion that prevention must be an important part of the agenda of geriatric psychiatry.

The traditional public health view derives from infectious disease and is divided into primary, secondary and tertiary prevention. Primary prevention is directed toward maintaining health by isolating the causes of disease and eliminating or counteracting them. Secondary prevention is directed toward enhancing recovery by case identification and prompt intervention early in the course of illness. Tertiary prevention is directed toward those already ill and emphasizes treatment and rehabilitation[4].

There is a growing consensus that the traditional public health view is not optimal. The components of this approach, including, for example, concepts such as pathogens, risk factors, disease vectors and definitions of caseness, do not translate easily into psychopathology or chronic disease. The 1994 IoM report[1] adapts a scheme developed by Gordon[5] to characterize preventive interventions as universal (targeted to a general population), selective (targeted at individuals at increased risk) or indicated (targeted to individuals with minimal levels of signs or symptoms).

Universal interventions are broad public health measures intended for an entire population or for significant geographic, socioeconomic or categorical subgroups within it (e.g. rural residents, low-income older persons, or pregnant women). Universal interventions (e.g. iodizing salt) may reduce risk for a large segment of a population but in all likelihood do not have impact on those already at high risk or those who would not have been at risk at all. Cost–benefit assessment is a clear decision criterion for the development and implementation of universal interventions, since they would, by necessity, involve exposure of many individuals not at risk for development of an illness.

Selective interventions are targeted toward those individuals at significantly increased risk of developing the particular illness or condition. Genetic loading and positive family history, other illnesses, or psychosocial or environmental transitions are all examples of factors that might be used to target selectively preventive interventions. Although selective interventions may seem easy, careful efforts are needed to assure proper identification and to avoid stigmatization or unnecessary fear.

Indicated interventions are targeted on those individuals who are already symptomatic and in whom early intervention may alter the longitudinal course or optimize the outcome of the illness. The underlying assumption is that significant advantage is gained when preventive interventions are extended to concerns with function and disability in those who already have an illness. Interventions directed at minimizing post-treatment relapse or recurrence would also fit within this category[41].

Following recommendations of the National Advisory Mental Health Council[6], this chapter is based on assumptions that an appropriate approach to prevention must: (a) be tied closely to treatment; (b) have strong connections to service systems and services; and (c) be based upon models of etiology, pathophysiology and risk. Following Kraemer *et al.*[7] we use "risk" and "risk factor" narrowly to indicate an empirically demonstrated agent or exposure that influences the likelihood of an event in a defined population. Preventive interventions are those directed at reducing risk of the development, exacerbation or adverse consequences of mental disorders.

PREVENTIVE INTERVENTIONS IN THE CONTEXT OF TREATMENT

Prevention of Relapse and Recurrence

Establishment of the efficacy of treatments is one of the major accomplishments of geriatric psychiatry research. As outlined in other sections of this text, many studies have demonstrated that older patients respond robustly to treatments that are appropriately applied with adequate intensities. These data are, largely, based on relatively brief, randomized controlled trials addressing the short-term efficacy of treatments to manage the symptoms of serious illnesses like depression[8] and Alzheimer's disease[9,10]. More recently, the prevention of relapse and recurrence has emerged as a major orientation in the treatment of the older patient. As the recognition has grown that most mental disorders in late life are chronic, recurring illnesses with substantial residual disability[11], so too has the acknowledgement that treatment must be approached with a much longer-term perspective[12]. An intervention is preventive if acute treatment response is the starting point, with the major purpose of preventing relapse or recurrence and not managing symptoms.

Prevention of Side Effects and Adverse Reactions

Co-morbidity and the associated polypharmacy that comes from treatment of multiple conditions are characteristic of older patients. New information on the genetic basis of drug metabolism and on the action of drug-metabolizing enzymes now provide us with important perspectives on clinically significant alterations in drug concentration levels or on complex drug interactions[13]. For example, many of the newer antidepressant agents, the selective serotonin reuptake inhibitors (SSRIs), compete for the same metabolic pathway used by β-blockers, type 1 C antiarrhythmics and benzodiazepines.

Many older patients require antipsychotic treatment for the management of behavioral disturbance in schizophrenia, depression and Alzheimer's disease. Movement disorders are common side effects of the older types of these medications, the conventional neuroleptics. Although doses tend to be quite low compared to doses used in young or mid-life adults, age and length of treatment represent major risk factors for the development of movement disorders[14]. Recent data suggest the possibility that the newer antipsychotics present a much lower risk and that the development of tardive dyskinesia may be preventable through use of different medication[15]. Trials of agents (e.g. antioxidants) hypothesized to treat these side effects have been proposed, although the data from some of the early studies have been inconsistent[16,17].

Many drugs affect body sway and postural stability, although there is substantial variability within classes of drugs[18]. In older patients, where the prevention of falling is a major concern, a preventive strategy would reflect a differential selection of treatments or development of fall-specific preventive interventions[19].

PREVENTIVE INTERVENTIONS IN THE CONTEXT OF SERVICES

Prevention of Suicide

Recognition of mental illness in older patients is highly variable. Changes in cognition, affect, thinking, sleep, etc. are often attributed to normal processes of age-related change by older people themselves, their spouses and close family members, and even by their family doctors and primary care physicians. The most tragic result of the failure to recognize illness is suicide. Suicide rates increase with age, and men always outnumber women in suicide completion. In most countries, older men generally are at the greatest risk of suicide. In the USA, for example, old White men have a rate of suicide six times that of the general population. Psychological autopsy studies show that depression is common among these men but that it is rarely recognized. Nearly 40% of the men who kill themselves see their primary care doctors in the week of their death; nearly 70% in the month of their death[20]. An uncontrolled field experiment on the island of Gotland in Sweden suggested that a depression-orientated educational intervention directed toward primary care physicians could reduce suicide[21]. Other approaches to the prevention of suicide, using aggressive outreach and case-finding techniques, have been developed in the context of community-based mental health or aging services[22,23].

Prevention of Premature Institutionalization

Nursing home placement typically comes at the end of a long and difficult period of caregiving by the families of patients with Alzheimer's disease. The burden of this caregiving in terms of stress, depression and quality of life has been extensively documented[24]. It is only the rare (and very wealthy) family that can provide the care necessary to maintain a patient with Alzheimer's disease at home; institutional care is required for virtually all patients who survive to the end-stage of the disease. From a public health perspective, delay of institutional placement until it was absolutely necessary could have significant impact. In an important randomized controlled trial of a family-based counseling intervention, Mittelman *et al.*[25] demonstrated clear benefit: a delay of over 300 days in nursing home admission for patients whose families were randomized to receive the treatment. The counseling intervention also resulted in a significant reduction in depressive symptoms in these caregivers. Clinical drug trials in Alzheimer's disease have begun using institutionalization as a primary outcome[26] or as an outcome from open-label follow-up after the trial had ended[27].

Prevention of Excess Disability

The concept of excess disability is a classic one in geriatrics[28] and refers at its core to the observation that many older patients, particularly those with Alzheimer's disease, are more functionally impaired than would be expected on the basis of the stage or severity of their mental disorder. There are many sources of this excess disability: some are medical, some are psychosocial and some are environmental. A generation of research has clearly demonstrated that attention to these issues, and aggressive intervention where appropriate, will prevent excess disability and will optimize levels of function.

MODELS OF ETIOLOGY, PATHOPHYSIOLOGY AND RISK

Biological Models

Improved understanding of the etiology and pathophysiology of mental disorders can potentially lead to interventions that will prevent the onset or progression of disease. A useful model here is the large simple trial in a broad population; incident cases represent the primary outcome. The state of our knowledge is not yet sufficiently well developed to support this type of research.

Nonetheless, there are some interesting possibilities developing as we learn more about oxidative and inflammatory processes, apoptotic mechanisms, hormonal correlates and genetic factors in disease. One possible example is the area of vascular depression. Several different lines of evidence are now supporting the conclusion that one form of late-onset depression has a cerebrovascular etiology[29]. Trials of vascular agents could use incident depression as outcomes.

Genetic Models

The genetics of mental disorders is an area of expanded activity[30]. Notably, several genes are now implicated in different forms of Alzheimer's disease. At present, the genetic correlates of mental disorders are not sufficiently specific to be used for purposes of population screening. It is entirely conceivable, however, that trials directed at delaying onset of disease, or directed at minimizing excess disability, could be launched using some of this genetic information as a basis for subject selection.

Clinical Models

Co-morbidity is one of the hallmarks of mental disorders throughout the life course. In late-life mental disorders, the most frequently observed co-morbidities are physical illness and brain disease. This provides a possible opportunity for preventive interventions; we present a few examples.

Visual impairment is common among older people; there is a high frequency of depression among older persons with impaired vision, and the depression is more strongly predictive of disability than is the vision loss[31]. The vision clinic would seem to be an appropriate location for the development of programs orientated to the prevention of depression in older patients. Similarly, aggressive intervention in depression has the potential for minimizing disability and optimizing function. This latter point is supported by a broad range of studies demonstrating that depression compromises the outcome of rehabilitation in stroke, Parkinson's disease, heart disease, pulmonary disease and fractures[32]. Research has also demonstrated that treatment of depression can significantly improve outcome of treatment and rehabilitation for the co-morbid physical illness or condition[33,34].

Complex programmatic interventions have been shown to have efficacy in the area of prevention as well. Ray *et al.*[19], for example, show how an intervention directed at safety with appropriate use of wheelchairs, psychotropic drugs and provision for transfer and ambulation, has a significant impact on the reduction of falls in nursing homes. In the outpatient setting, multidisciplinary comprehensive assessment resulted in significant improvements in the detection of depression and cognitive impairment and resulted in substantially reduced risk for nursing home placement[35,36].

Psychosocial Models

Bereavement is perhaps the prototypical psychosocial risk factor in late-life mental disorders[37]. Considerable research has been devoted to the exploration of bereavement-related depression, complicated grief, traumatic grief and similar constructs[38–40]. It is entirely conceivable that preventive interventions for those with complicated grief could have major impact on both mental and physical health. It is also conceivable that greater understanding of the correlates and predictors of complicated or traumatic grief may lead to the design of earlier-stage interventions, directed at modifying the likelihood of developing the risk factor in the first place. Interventions directed toward risk factors, rather than toward disorders, may be properly considered to be primary prevention.

CONCLUSION

In this chapter we have presented the broad parameters of a programmatic approach to prevention in late-life mental disorders. There is no established approach to prevention research that could be easily adapted to meet the needs of the field. Approaches to prevention need to be based in the deep foundation of knowledge in treatment and services research. They must be built upon improved models of etiology, pathophysiology and risk. A new approach to prevention holds the promise to be a significant development for the field. We have no doubt that success is achievable.

A Damning Analysis of the Law and the Elderly Incompetent Patient—Rights, What Rights?

Peter Edwards

Peter Edwards & Co., Hoylake, UK*

Does the legal process provide a framework in the UK for protecting the rights of those who lack the capacity to make their own decisions? In what way should the law impact on families, professionals and carers? Surely you, the practitioner, you the carer, you the family member take decisions on what you believe to be in that person's best interests? You are there to do a good job exercising sound judgements. You are motivated by a desire to protect, to support and to make safe decisions in the best interests of the incapacitated person. You surely do not want to be impeded by considerations of an incapacitated person's legal rights. But what if the person him/herself wishes to make a different decision? You may consider it unwise or even risky for him/her to follow his/her desires. On what legal basis does one citizen override the ability of another to exercise choice? Who decides?

DOES THE LAW HAVE A ROLE?

Why is the law of incapacity/incompetence so important when it comes to protecting rights? For a person with capacity, the law recognizes the right to take responsibility for decisions. However, we must then bear the consequences of those decisions. Incapacity equates with society's view that incompetent adults may have to be protected. They may lack the ability to realize the consequences of the exercise of their decisions and that could place them at risk.

The dilemma is therefore apparent. At some point we cross that invisible divide between capacity and incapacity; between the right to make unsafe decisions and the right to be protected from them; between taking responsibility and the loss of the power to exercise our own judgement; between having enforceable rights and not.

For those who are deemed to lack capacity, the responsibility for deciding what is in their "best interests" may lie with those for whom there is a conflict of interest. They may be going to inherit the estate or they may even be those who are perpetrating abuse. The state of UK law leaves the incapacitated ripe for exploitation. Proposals for a change in the law appear to have stalled.

Perhaps when it comes to making a will, preparing an enduring Power of Attorney or protecting someone's financial affairs from fraud or exploitation, it is easy for us to accept the need for a protective framework. However, what about the concept of enforceable human rights? When should the elderly be allowed to take risks?

We, ourselves, have rights and we can take steps to enforce them. But if we have lost the capacity to fight for or defend our rights, what then? When we have lost capacity, is there a right that restrains the distribution of our confidential information? "I don't want to go into a nursing home." "I want to choose with whom I live and with whom I have a personal/sexual relationship." "No, whatever they say, I do not believe that my children are acting in my best interests." Who will enforce my rights now? Who will listen?

On 2 October 2000, the UK Government belatedly brought into force the Human Rights Act 1998 in England. It sets out the rights and responsibilities of the citizen and provides a framework based on the European Convention of Human Rights and Fundamental Freedoms. It provides a baseline of rights below which the citizen should not be allowed to fall and introduces a rights culture laid on our domestic legislation. The indications are that it could have far-reaching effects on the practice of old age psychiatry, as well as impacting on the causes of action open to an increasingly aged population when their rights and opportunities are infringed.

The greatest impediment to the development of a rights-based system is the identification of the individual who will act on behalf of the incompetent client. Who will make the bridgehead to the lawyer? Who will blow the whistle? How does the incompetent client get to know of his/her rights in the first place? What happens when we cannot trust the families? The questions are easier to identify than the answers.

ROLE OF THE LAW

The role of the law must be viewed within the context within which it prevails. At present there is no doubt that in the UK[a] the percentage of the population reaching the traditional retirement age[b] is increasing and has done so since the post-war boom of the 1950s and 1960s. This, of course, has both political and financial ramifications. Linked to this has been a gradual increase in income, disposable assets such as homes, cars and other property, as well as a notable increase in the number of elderly people with their own assets.

*A specialist mental health law firm.
[a]Unlike the Republic of Ireland, where the average age of the population is 28 years of age.
[b]65 for men and 60 for women.

In examining a rights-based culture, it is relevant to remind ourselves that a notable shift emerged during the Conservative/Thatcherite years from 1979 onwards, when notions of solidarity and community waned and a ''self'' culture emerged.

What does all this mean in the context of the law, elderly people and incapacity? What does it mean within a society focused on ''self'' and where there are a greater number of assets and a greater number of people who need to have their rights protected?

Capacity is a concept based in our common law. Therefore, those with the final say are the judiciary. However, rarely is the law asked to be the arbiter of individuals' capacity. Where there is dispute, it is always possible to seek a declaration from the courts. In practice, however, the final decision is taken by the myriad of individuals who come into contact with the incapacitated person. It could be the doctor, the nurse, the social worker, the staff in the nursing home or even the family. When it comes to medical treatment, the doctor who is in charge of treatment has the responsibility to make that decision. Some believe that only psychiatrists can perform this task. Psychiatrists get called in unnecessarily by other doctors (e.g. general practitioners, surgeons or anaesthetists) who do not seem to realize that they themselves are responsible. Usually those who are deciding on capacity have no concept of the test to be applied and merely assert that the individual will now have decisions made for him/her. It is a chilling scenario, particularly as many of us may eventually be in this predicament.

It is worrying that at times, medical staff, without any consideration of capacity, seek to obtain consent to a medical intervention from a person who does not have the capacity to consent. If that patient declines to agree with the treatment, then it is not given. It could perhaps have been justified by the common law doctrine of necessity. Failure to treat under those circumstances could amount to negligence.

Any process that purports to be based on a rights-based system must not be arbitrary. There should be a clear framework within which decisions are made. This should particularly be so when the essence of the decision is to strip away from the individual the right of autonomous decision making.

OBJECTIVES

What should be the guiding objectives and principles upon which any such decisions are to be based? Further, how is capacity to be assessed and what are the tests that the law will endeavour to apply?

When the citizen turns to the law to find an answer, it soon becomes apparent that in the UK it is a mess. There is not one separate body of law established to deal with elderly incapacitated people. However, what can be determined from the case law and statutes that do exist, is that the law has constructed a number of overriding objectives.

First, there are the means by which the duties that are owed to those who lack capacity are enforced. This can be illustrated in financial and property matters, where the Court of Protection can be invited to intervene[c]. A Receiver can be appointed to take control of a person's financial affairs and the Receiver is answerable to the Court. The great weakness here is that professionals and others who have concerns about the possible exploitation of an incapacitated individual will often know little of this remote and distant Court. It only has one base, and that is in London. What is more, those who are aware that exploitation is taking place may be the very people who are perpetrating it. Who then will activate the process?

Whilst we have capacity, it is possible to make plans that would result in avoiding the costly involvement of the Court of Protection. It is possible to complete a simple document called an Enduring Power of Attorney. This must be completed whilst a person still has capacity and allows one to appoint the individual(s) who will control one's financial affairs when and if one loses capacity. The simplicity of the process can allow those determined to abuse to prevail on the vulnerable person, who may even lack the capacity to execute the document. The principle is that, as we have capacity, we have the right to make unwise decisions. When capacity is lost, the Enduring Power of Attorney becomes effective by registering it with the Court of Protection. This is essentially an administrative task.

Second, the law can be invited to consider what is in the ''best interest'' of the incapacitated person. This can involve the right to be supported and to be legally represented. However, if the criteria for appointing a receiver under the Court of Protection are met, then the incapacitated person cannot instruct a solicitor or bring legal proceedings in his/her own right. This role must be undertaken by a ''litigation friend''[1]. This objective is further endorsed by the Human Rights Act 1998 which sets out to promote the fundamental rights, freedoms and liberties of UK citizens. Article 6 protects the right to a fair trial. The difficulty arises when seeking a mechanism to achieve this. Yet again, the process of protection is entirely dependent on someone making the link between the incapacitated person and the judicial process.

Third, and perhaps most significantly, is the role of the law to protect individuals from ill-treatment, abuse, neglect and exploitation. The forms that these take are endless and nauseating, as we see in the range of daily media reports illustrating that people know no bounds in gratifying their excesses against vulnerable people, in areas such as money, possessions and physical and sexual abuse. The obvious difficulty in using the criminal justice system is that the abused person may not have sufficient capacity to give evidence. Unless there is separate, corroborative evidence the perpetrator may go unpunished.

PRINCIPLES

The above objectives are not, and in fact cannot be, freestanding. They are guided by a set of prevailing principles that are transferable to the development of the law itself.

In exploring the principles, it should be noted that much research was done by the Law Commission[2] and the Lord Chancellor's Department[3] in the area of Capacity.

In UK law, all adults are presumed to be competent and as such will have the same rights and opportunities as others. The burden of proof therefore lies on those who seek to assert the citizen's lack of capacity. Where there is the need to interfere in the lives of those who lack capacity, any such intervention should be the minimum required in the circumstances. Where an individual has been found not to have capacity, nevertheless, he/she should be encouraged to take the kind of decisions that he/she might have taken before capacity was lost. This may sound like an effective set of principles. However, they need to be set in their practical context.

Sadly, it may be in the interests of everyone concerned that the individual should be treated as if he/she were no longer capable of making his/her own decisions. After all, an elderly person may want to make a decision that we might consider unwise, foolish or

[c]Court of Protection is an Office of the Supreme Court and the provisions cited are to be found in s. 93 of the Mental Health Act 1983.

even dangerous. That person could be your mum or dad, who may want to give money away or enter into a close relationship with someone many years younger; your inheritance might be threatened. Asserting his/her incapacity could protect your finances. Or a situation might arise where the elderly person does not like the rules and regulations in the nursing home. He/she may find him/herself being treated as a child. "No, you cannot go out; here is your medicine you must take it; it is time for bed now; what we are doing is in your best interests." Who has proved his/her incapacity? Who has even thought about it? Rights can be very uncomfortable.

The courageous professional who correctly asserts that a person has capacity and that he/she may take responsibility for his/her own decisions may be left vulnerable to criticism and even attempts at litigation. Defending the decision when some damage or loss has ensued against an irate family member or community can be an uncomfortable business. This takes knowledgeable and confident professionals.

Therefore, the confidence of professionals and others who are called upon to exercise these judgements is crucial, as is the extent and timing of the intervention. The law has a further role in determining whether and to what extent the intervention by the state has been *proportionate* to the presenting facts and evidence. A proportionate response is an important concept in the Human Rights Act.

Before concluding this section on the role of the law within the context of incapacity, there is an often-overlooked area, namely the role of the lawyer. The role of the lawyer can become confused if the lawyer has not posed to him/herself the vital questions: who is my client?; who am I actually acting for?; to whom do I owe my professional responsibility?; is it the vulnerable elderly person or the family member? The lawyer has to be alert to the situation in which he/she is requested to advise the family who are trying to use the law to exploit the incapacitated individual, e.g. by assisting the family in obtaining an Enduring Power of Attorney (see above) from someone who, had the proper enquiries been made, would have been found to lack capacity (and therefore unable to execute the deed).

WHO LACKS CAPACITY?

Most decisions about capacity are made without any thought at all about objective criteria. Doctors, nurses, social workers, families, or nursing home owners will simply assert it as a fact in order to justify overriding the wishes of the individual.

As indicated above, the Court is the ultimate arbiter of the issue of capacity. However, in those rare cases where it is asked, it is misleading to believe that the judge will arrive at some clear and objective decision when the very criteria for analysis are based partly on the shrouded mystic of clinical analysis and partly on societal attitudes. Essentially there are no clear criteria and it is not good enough simply to assert that each case will be decided on its own facts. The Human Rights Act should cause a shift in emphasis, where the starting point will be the rights of the citizen. Article 6 guarantees the right to a fair trial. The problem may be, who is going to enforce this? The judiciary will have to be alert.

THE BURDEN OF PROOF

When making this decision, the law asserts that a person is presumed at common law to have legal capacity unless it is shown that they do not. However, it is the medical practitioner who may seek to assist or convince the court of the lack of capacity. If such a question comes before the Court, the law at present places the burden of proving such incapacity on the person who asserts it (on a balance of probabilities, e.g. 51/49). In itself this is worrying, as a diagnosis of incapacity may lead to the loss freedoms, rights and liberties which, our society says in other contexts, namely criminal justice, require that a much higher standard of proof should be reached. Bearing in mind the consequences of a finding of incapacity, surely the standard of proof to rob a person of the control of his/her own affairs should be a much higher one (i.e. beyond all reasonable doubt).

THE HERE AND NOW TEST

An important principle needs to be understood. In assessing a person's capacity, the law will seek to do so at the relevant time in respect of the particular activity/transaction that the person is about to enter into. Anyone assessing an individual's capacity must apply this test. It is possible that a loss of capacity may be transient or episodic. In the early stages of dementia it may be the subject of partial remission.

What is more, a person may both have and lack capacity at the same moment in time. There are differing tests to be applied, e.g. when making a will, entering into a contract, consenting to marriage or sexual activity, making an Enduring Power of Attorney or consenting to medical treatment. When looking at the statutory test of incapacity to be applied when applying to the Court of Protection to appoint a Receiver to manage the property and (financial) affairs of an incapacitated person, it is required that the person must be incapable "by reason of mental disorder". This is defined at Section 1 of the Mental Health Act 1983.

A person may lack the capacity to make a will but possess sufficient capacity to go shopping or vote. Unless it really is the case, we should refrain from defining a person generally as "incapacitated".

There are various ways of approaching the assessment of capacity. The three key methods were usefully outlined in the Law Commission Consultation Paper[4]. The three approaches are:

- *Outcome*. Capacity is determined by the content of the individual's decision.
- *Status test*. May apply in respect of age/diagnosis, etc. without further consideration of the individual's actual competence.
- *Test of understanding*. This concerns an assessment of whether the particular individual is able to make a particular decision at a particular time.

It is the last of these that applies in our common law and which in fact was proposed by the Law Commission in its *New Jurisdiction* publication of 1991 to form the basis of a statutory test.

As can be seen above, a range of different specific tests exists for particular instances, but normally general principles apply which substantively are based upon the individual's understanding, rather than the exercise of his/her judgement. If we were to be judged by the appropriateness of the decisions we make, incapacity would be a far more common concept!

Having noted the very variable application of the framework, it is disturbing to note that little if any research has been undertaken to determine the skills and abilities necessary to establish capacity[5].

EVIDENCE

Regardless of the above criteria, from an evidential position mental incapacity is a question of fact and there can be no doubt that the correct legal test must be applied. That, as alluded to above, will vary according to the circumstances. The role of the judge within the court proceedings is seeking to determine capacity as a lay person, influenced by personal observations

and on the strength of evidence submitted from doctors and others who know of the individual[d]. In the words of His Honor Mr Justice Nicholas Wall:

> Expert witnesses need to remember that most judges do not have any more medical expertise than the average intelligent lay person . . . it is for this reason that they rely upon the integrity of expert witnesses[6].

THE "NEXT OF KIN"

Our nearest blood relative. Our kind and loving family. Those who are only capable of acting in our best interest. Surely, in the legal lacunae of decision making they are the legal rock on which we can build. If we are incapable of making decisions for ourselves, then surely professionals must turn to them to sanction actions. They know the best way to spend our money, they know when we should be going into a home, they know what is best. Really? Are you sure?

IN WHOSE BEST INTERESTS?

The UK law confers no legal rights on the "next of kin" *per se*. The matrix of decision making for a person who lacks capacity is our common law doctrine of necessity. This involves four basic elements:

- The person must lack capacity in relation to that particular decision at that time.
- It must be sufficiently necessary to make that decision.
- The person making it must be reasonable.
- It must be in the best interests of the incapacitated person (not the next of kin and not the professional).

All too often the professionals may feel powerless in the face of families who are demanding admission to a nursing home, or a discharge from hospital. They may be trying to insist on a particular form of treatment or withholding their consent to what the medical team is proposing. The professionals know that no "reasonable person" could possibly believe that certain decisions were in the incapacitated person's best interests. But, the family want it, so how can I possibly prevent it? The lawyer would point out that if the professionals capitulate and damage ensues, that it could be called professional negligence.

TREATMENT

To have capacity gives us the right to refuse any treatment that we do not wish to receive, even if death would be the result. Only in the case of people detained under the Mental Health Act can a competent adult be treated against his/her wishes, and then only for his/her mental disorder.

Clearly drawn and unambiguous "advance refusals" (otherwise known as living wills or advance directives) allow persons with capacity to bind the hands of the doctors. They can indicate that in the event of them becoming incapacitated, there would be certain treatments that, had they retained capacity, they would not have consented to. These have emerged through our case law, notably the case of *Airedale NHS Trust v. Bland* [*1993*] *1 All E.R. 821* and are a common law concept. An advance refusal could only be overridden if either it was not sufficiently clear or the person was then "sectioned" under the Mental Health Act because he/she required treatment in a hospital for mental disorder. Our statute law always takes precedence over common law principles.

WHEN TO "SECTION" UNDER THE MENTAL HEALTH ACT

From my own experience of training mental health professionals for many years, few professionals working with the elderly seem to realize that the Mental Health Act provides a framework of protective powers for those who lack capacity and have a mental disorder. This term includes the mentally ill. Dementia is of course a form of mental illness.

The Act allows a person to be "sectioned" when his/her mental disorder is of a nature or degree that requires either assessment (section 2) or treatment (section 3) in hospital and his/her health, safety or the protection of others require it. Once sectioned it allows the professionals to impose their will on the patient but certain boundaries are proscribed. It gives the individual certain rights of appeal, and these can be triggered simply on the basis that the right has not been exercised.

Since the House of Lords judgement in the case of *R v. Bournewood Community and Mental Health NHS Trust ex parte L 1998 3 W.L.R. 107*, the incompetent patient need only be sectioned if it is necessary to treat him/her in hospital for a mental disorder and he/she demonstrates actual objection by word or deed. Because statute law (that passed by Parliament) takes precedence over our common law, the person should be sectioned, and if he/she is not, then any treatment given under the common law doctrine of necessity would amount to unlawful imprisonment and assault. You cannot use the defences available under common law if you are obliged to apply the statute law. At present, it would seem to me that few medical and nursing professionals realize this. The guidance issued by the Department of Health[7] following the Bournewood judgement tells us that if there is doubt as to whether the action amounts to an objection, then it is to be treated as if it were an objection. The incapacitated person who is trying to leave the ward or is objecting to medication (e.g. spitting it out), where there is doubt, should be considered for a Mental Health Act section. This would then accord him/her rights under that Act. It would then follow that further treatment for mental disorder under common law would be unlawful.

What about the person who is "required" to go into a nursing or residential home and does not wish to go? The Code of Practice to the Mental Health Act, Chapter 13 paragraph 13.10.b., indicates that, under these circumstances, Guardianship under the statutory powers in the Mental Health Act should be seriously considered.

> Where an adult is assessed as requiring residential care, but owing to mental incapacity is unable to make a decision as to whether he/she wishes to be placed in residential care, those who are responsible for his/her care should consider the applicability and appropriateness of guardianship for providing the framework within which decisions about his/her current and future care can be planned.

Few professionals seem to realize this.

A Guardianship Order allows a guardian to require a person to "reside in a particular place", attend various places for occupation, education or treatment or to allow access to the person on Guardianship by specified third parties or the guardian.

[d]This proposition is strongly supported in the High Court Judgement of Wall J in Re: G (Minors) (Expert Witnesses) [1994] 2 FLR 291, 298.

Although the use of Guardianship is increasing with the elderly (Mental Health Act Commission 7th Biennial Report[8]), it is still used infrequently. There were 804 Guardianship cases current at 31 March 1998 compared with 335 in 1992. This, however, includes all age groups and mental disorders. There are no statistics available specifically for the over-65s. Usually the common law doctrine of necessity is invoked and this allows reasonable force to be used where necessary, either to prevent a person leaving or to restrain him/her for medication or other reasons. This is likely to be subject to challenge under the Human Rights Act 1998. There is a strong possibility that the Bournewood case will be overturned by a decision of the European Court of Human Rights. This is because, under Article 5, there is a Right to Liberty and Security of the Person. This states under Article 5(4) that:

> Everyone who is deprived of his liberty . . . shall be entitled to take proceedings by which the lawfulness of his detention shall be decided speedily by a court and his release ordered if the detention is not lawful.

For those who lack capacity and are "detained" under common law there is not a mechanism that allows this challenge in English law.

THE NEW ERA OF HUMAN RIGHTS

With the passage of the Human Rights Act 1998 we are entering a new era for the concept of human rights in the UK. With the partial incorporation of the European Convention of Human Rights and Fundamental Freedoms there is the opportunity for the citizen to take proceedings against public bodies for alleged breaches of human rights. Public Bodies would include state and private hospitals, social service authorities, doctors and social workers who can carry out specific functions under the Mental Health Act where any of these bodies are carrying out a public function. As appears usual in the legal process, the mechanism by which the incapacitated can seek to assert their rights is far from clear. Yet again it will require the identification of the individual who will take the proceedings on their behalf.

The most relevant Articles to the European Convention of Human Rights and Fundamental Freedoms are:

- Article 2 enshrines the right to life. This includes the right to be protected by those who are caring for the vulnerable from risks that may lead to death.
- Article 3 protects the citizen from torture, inhuman or degrading treatment or punishment.
- Article 5 states that there is a Right to Liberty and Security of the Person.
- Article 6 protects the right to a fair trial when, for example, the Court of Protection is considering removing a person's right to control his/her own financial affairs.
- Article 8 provides for respect for a person's home and family life. This would include decisions about confidentiality of information, where a person lives or with whom he/she has contact.
- Article 12 provides for the right to marry (despite one's age!).

IN CONCLUSION

With an inadequate legal framework, extensive abuse taking place in many guises, with those working with the elderly often unaware of what the law permits, with the government apparently unwilling to legislate, the future looks bleak. The Human Rights Act could and should be about changing our culture. It should affect the way that we conceptualize the exercise of decisions that affect the rights of the citizen. My fear is that in all other areas of society this may well be the case. However, for the elderly confused incapacitated person, who will take on responsibility for this awesome responsibility?

Older People, Clinicians and Mental Health Regulation

Elaine Murphy
Queen Mary College, University of London, London, UK

The Mental Health Act 1983 (England and Wales) made no mention of age, applying to children and those of advanced years just the same as to younger adults. Similarly, the Mental Health Act Commission created by the 1983 Act to "keep under review the operation of the Act" as it related to detained patients also had no responsibilities specific to older people. The old Commission had an awkwardly circumscribed role with few real powers. It visited hospitals and registered nursing homes to meet patients and ensure that the conditions in which they were detained were of an acceptable standard. The Commission also investigated complaints relating to detained patients and monitored the consent to treatment safeguards in Part IV of the Act, appointing independent doctors to give second opinions.

In December 2000, after 10 years of discussion and consultation about the failings of the 1983 Act, the government published proposals for a new Mental Health Act[1], which will have a very significant impact on the practice of geriatric psychiatrists. It contains new safeguards for the care and treatment of people with long-term mental disorders in institutional care, providing obligatory second opinions for those who are unable, through mental incapacity, to consent to treatment. In effect, this will cover all those with dementia in long-term care and many other older psychiatric patients. The new Act also replaces the old Commission with a new Commission for Mental Health, which will have wide powers in relation to overseeing the new legislation but will not be a visitorial or inspectorial body. For the first time, the new Commission will have a responsibility to ensure that professionals are trained properly in the legislation. This will surely require far closer working relationships with professional training and accreditation agencies. The old visitorial function, however, will be handed over to the new National Care Standards Commission and the Commission for Health Improvement. Thus, clinicians can expect even more inspection and regulation, rather than less, under the new regulations.

The central regulatory system is usually dated back to 1833, when the Factory Inspectorate was established. *The Times*[2] pronounced that this new system contained "the seeds of mighty changes", although the Editor was "no enthusiast" for central regulation but acknowledged that an inspectorate offered advantages "if inspectors or visitors of strong capacity, of enlightened humanity and moral courage" were appointed. The Lunacy Commission of 1845, chaired by the indefatigable 7th Earl of Shaftesbury for 40 years until his death in office, achieved considerable influence with government and changes in local asylums and workhouses because the Commission remained small, elite and adopted a coherent, unifying set of policies in its early years[3].

Modern mental health commissions are similar to the Lunacy Commission in being only as effective as their members are. Ministers have not always been convinced of this simple truth and have sometimes seen Commission appointments as a convenient reward for other fields of endeavour or as an opportunity to promote other laudable government objectives. Since its inception in 1984, the old Commission, a multiprofessional body, struggled to attract members of distinction from the professions of psychiatry and law and yet, to achieve credibility and respect from psychiatric services, the quality, training and behaviour of members was crucial. Over the years there was a steady improvement in the administrative efficiency of the organization and a significant step up in quality of the recruits. The new Commission will need to learn some of the lessons learnt if it is to achieve early credibility. Being a good commissioner requires enormous tact, humility and an ever-present awareness that a nurturing, developmental, encouraging approach achieves far more and is less alienating to professional staff than a heavy-handed "policing" approach.

The notion underpinning regulatory bodies dies hard. The idea is that the Secretary of State employs a team of quasi-independent "eyes and ears" to act as the conduit for information to central government and to channel edicts from the centre to the field. The proliferation of statutory commissions and non-statutory regulatory bodies (so-called QUANGOS) in the late twentieth and early twenty-first centuries would suggest that faith in these institutions as movers and shakers of social improvement remains undimmed in governments today. The zeal with which agencies are established falls away as soon as it is realized that inspectors and monitors cannot substitute for good local managers. In mental health services, good hospital unit management and improvements of standards of training and clinical work through professional bodies, such as the Royal College of Psychiatrists and the National Boards for nursing education, are more likely to effect permanent improvements in standards of care. "Watch-dogs" and Commissions inevitably disappoint ministers and the usual cycle of events is that a commission's powers are progressively reduced and in due course frequently disbanded on the grounds of economy. As the numbers of factories grew beyond what it was reasonable to inspect, the Factory Inspectorate's sweeping powers to make statutory regulations and act as local magistrates were abolished in 1844. The Board of Control similarly found its powers diminished from those of its predecessor, the old "dead duck" Lunacy Commission, and was

finally abolished in 1959. More recently, the Health Advisory Service, established by Richard Crossman's health ministry in the 1960s, was perceived to be unable to stop hospital scandals and was gradually denuded of its powers and eventually extruded from agency status to make a living from consultancy as best it could. Now the Mental Health Act Commission predictably gives way to a new-style Commission, with more circumscribed, focused powers, and it remains to be seen whether the new one will fare any better in the eyes of services and the government than the old one.

It has been estimated that there are approximately 44 000 informal admissions to institutions annually in England and Wales of mentally incapacitated patients who are compliant with treatment but lack the capacity to consent to treatment[4]. This far exceeds the 13 000 detained under formal powers. The new Act will provide them with extra safeguards, the right to a second opinion for long-term treatment and the right to appeal to a Tribunal. Some psychiatrists will regard an extension of legal powers to informal incapacitated patients as an unwelcome extra burden of work on them and their clinical teams. On the other hand, the new provisions will ensure that older people will receive greater attention from the regulatory bodies and their legal rights to decent care and treatment will be enhanced.

When they work well, central regulatory Mental Health Commissions can be strong allies to clinicians seeking to improve their patients' lives. Psychiatrists need to understand the role and remit of the Commission and be willing to serve during part of their career. The effectiveness of the new Commission will be greatly enhanced if the profession adopts a strategy of supporting and involving itself in its work and also ensures that the needs of older people are kept firmly in the forefront of the regulators' considerations.

Training Requirements for Old Age Psychiatrists in the UK

Susan M. Benbow
Wolverhampton Health Care NHS Trust, Wolverhampton, UK

In the UK over the last 20 years, increasing numbers of psychiatrists have specialized in working with older adults. Various terms have been used to describe this area of work: "psychogeriatrics", "geriatric psychiatry" and "old age psychiatry" are probably the most common. In 1978 the Royal College of Psychiatrists formed a Section (now Faculty) of Old Age Psychiatry and just over 10 years later, in 1989, old age psychiatry became recognized as a specialty by the Department of Health. The Royal Colleges of Physicians and Psychiatrists produced a Joint Report in 1989, which devoted a chapter to education and training in the psychiatry of old age[1]. At that time there was no accepted training programme for psychiatrists aiming for a career in the developing specialty. Things have changed considerably over recent years.

BACKGROUND: GROWTH OF THE SPECIALTY

In the early 1980s, two surveys of psychogeriatric services[2,3] showed considerable growth in the developing specialty, such that over 200 consultants were identified by late 1983. At that time the Joint Committee on Higher Psychiatric Training of the Royal College of Psychiatrists required higher trainees to spend 12–18 months in posts where the bulk of the work was in the subject; 28 senior registrar placements were identified. The authors predicted ongoing growth in old age psychiatry and a need to expand available training.

By 1990 there were 360 consultants working mainly in old age psychiatry and in 1993 the total had increased to 405[4]. Figures collected by the Faculty of Old Age Psychiatry show that the total has continued to rise, although there is still a high vacancy rate of approximately 14%.

UNDERGRADUATE EDUCATION

The first Joint Report[1] recommended that each medical school should have a senior academic in old age psychiatry and that all medical undergraduates should receive training in the subject. Faire and Katona[5] surveyed undergraduate teaching in the UK and reported a considerable expansion of academic posts in the specialty, but noted that more than half of all departments lacked a senior old age psychiatry academic. Almost all medical schools offered formal lectures in the subject, but there was great variation in the amount of clinical experience on offer and the authors felt that there was a strong case for all medical students having clinical experience in old age psychiatry, as recommended by the Joint Report. Gregson and Dening[6] surveyed teaching hospital psychiatrists and found that many teachers set no formal learning objectives in old age psychiatry. Most respondents wanted their teaching to impart enthusiasm for the subject, a sense of hope in working with mentally ill older adults, and an awareness of issues specific to ageing and ageism.

Although there are now chairs or readerships at a number of medical schools in the UK, gaps remain[7] and the second Joint Report, published in 1998, recommends that the characteristics of mental disorders among older people and the principles of good quality care should be included in the core curricula of all schools of medicine and nursing.

POSTGRADUATE TRAINING

The total minimum duration of specialist training in old age psychiatry is 6 years, of which 3 years will be in general professional or basic specialist training and 3 years in higher training (as a specialist registrar).

Basic Specialist Training

Part II of the Membership examination of the Royal College of Psychiatrists (MRCPsych) can normally only be taken after 30 months of training in psychiatry and is a requirement for entry into higher training, so basic training normally lasts for about 3 years. The first 12 months may include 6 months in old age psychiatry, provided that the experience offered is broad and includes the assessment and treatment of people with functional mental illness. Experience in old age psychiatry during basic training is regarded as important because of the increasing elderly population and the high rate of mental illness in older people, but the College *Basic Specialist Training Handbook*[8] states that trainees should be exposed to acute and functional mental disorders in late life and not solely to organic brain diseases. Old age psychiatry placements can often offer good community experience for trainees and the opportunity to attract young psychiatrists into the specialty.

Basic training concentrates on providing a range of experience in the specialties and subspecialties of psychiatry, aiming to develop history taking, formulation and case presentation skills, therapeutic skills and clinical judgement, relationships with

colleagues, patients and relatives/carers, basic psychiatric knowledge and appropriate knowledge of general medicine.

By the time the trainee is ready to move into higher training, he/she will have completed a minimum of 3 years in approved training placements and will hold the MRCPsych[9]. He/she will also have some idea of his/her eventual career intentions. General psychiatry and old age psychiatry Specialist Registrar posts may be advertised separately, but trainees may opt to undertake training jointly in both specialties (see below).

Higher Specialist Training

Higher training aims to provide an educational programme to prepare a trainee for independent practice in old age psychiatry. The number of higher trainees is determined by the number of national training numbers (NTNs) and this is fixed centrally by the NHS Management Executive or equivalent body. The Specialist Training Committee of the Royal College of Psychiatrists (STC) sets the standard for training schemes and, under the aegis of the Specialist Training Authority (STA), sets the standard for award of certificates of completion of specialist training (CCSTs), which indicate that specialist training has been successfully completed. Since 1997 a CCST has been mandatory before taking up an NHS consultant post. Old age psychiatry falls within the remit of the Royal College of Psychiatrists' General and Old Age Psychiatry Specialist Advisory Committee (GOAPSAC)[10].

General and old age psychiatry higher training schemes may offer two options for aspiring old age psychiatrists. Single accreditation involves training for 3 years to gain a CCST in old age psychiatry. Currently these trainees may spend 1 year in general psychiatry or one of its subspecialties if they so wish. Single accreditation therefore necessitates a total of at least 6 years in psychiatric training. Many trainees (probably about 60%) opt to complete dual training, which aims at dual certification in general and old age psychiatry. These trainees complete a 4 year higher training programme, with 2 years in each specialty. They must have been appointed to their specialist registrar posts by an appropriately constituted appointments committee and will hold a NTN in old age psychiatry. Dual certification will require a total of at least 7 years in psychiatric training.

During their training, specialist registrars are expected to develop their professional attributes, core knowledge and skills, and are set goals in research and audit, teaching and supervision, and management. Currently, six "core" sessions are devoted to experience in old age psychiatry (or other specialty). "Core" experience involves working with a multidisciplinary team to provide a service to a defined population. Two further sessions are available for research, audit and personal study, and another two can be used to develop special interests. Old age psychiatry trainees are expected to gain experience of geriatric medicine at some stage of their training, and this is usually achieved either on a short-term attachment or using special interest sessions.

CONTINUING PROFESSIONAL DEVELOPMENT

Loane and Barker[11] surveyed newly appointed old age psychiatrists' views of their higher training. Overall clinical experience was felt to be satisfactory, but management experience was lacking in a number of areas and experience in dealing with complaints, dealing with difficult professional relationships, recruitment and disciplinary proceedings were all identified as areas where training was insufficient. Higher trainees are expected to get training in management but it can be difficult to pitch it at the right level.

The emphasis today is on lifelong learning[12], which is regarded as essential for all healthcare professionals. Old age psychiatrists are no different and are likely to see continuing developments in their field throughout their working lifetimes. Learning does not stop at the transition from higher trainee to consultant, and some might say that this is the point at which learning really starts. Consultants increasingly plan their CPD programmes[13], although these need to be flexible and to evolve with the specialty, the individual and the job. Increasingly too, consultants change their interests, disciplines and posts as their careers progress. This may be a way to re-energize and deal with the stresses of their multiple roles[14]. Continuing professional development should be a positive supportive opportunity for consultants to continue learning throughout their working lives.

LIFELONG LEARNING

Learning about old age psychiatry starts in medical school and continues throughout the working life of an old age psychiatrist. The context within which the specialty operates is constantly changing. There are various threats and opportunities on the horizon, including changes to the Mental Health Act[15], new ways of dealing with people unable to consent[16] and the National Service Framework for older adults. Old Age Psychiatry and its practitioners cannot stand still. The enthusiasm which teaching hospital psychiatrists aim to impart to their medical undergraduates can be maintained during specialist training and boosted throughout a consultant's career by continuing professional development and the challenge of working within a constantly changing health and social service context.

Old Age Psychiatrists and Stress

Susan M. Benbow

Wolverhampton Health Care NHS Trust, Wolverhampton, UK

Stress, and its effect on the workforce, is a matter of increasing concern in the Health Service. Stress levels in health professionals generally are high[1]. Doctors as a group have increased rates of cirrhosis, road traffic accidents and suicide, compared with the general population[2]. They are prone to symptoms of anxiety and depression, and are more likely to misuse alcohol or other substances[3].

WHY WORRY ABOUT SERVICES FOR OLDER PEOPLE?

Working with older people, especially those with mental health problems, might be particularly stressful, for various reasons. This client group is more likely to exhibit challenging behaviours. They are subject to the increasing disadvantages, disabilities and progressive loss of independence associated with increasing age, and are approaching death. Consultants (and other staff) in geriatric medicine and geriatric psychiatry are working in so-called "Cinderella specialties", which struggle to compete for resources with the more "sexy" acute specialties. The stigma of being old, mentally ill and cognitively impaired is contagious and affects attitudes towards the staff who work in these specialties[4]. In addition, staff will have to confront their own beliefs and fears about ageing, dementia and death for themselves and members of their own families[5].

It is not surprising, in this context, that psychiatrists are retiring earlier[6] and recruitment to the specialty is inadequate to maintain consultant numbers[7]. Stress is an important issue for the workforce.

WHAT DO WE KNOW?

Studies of the work patterns of old age psychiatrists have found that they have long working days with little opportunity for recreation, family life, personal study and research[8,9]. More than 40% of old age psychiatrists do extra work at home on every day of the working week except Friday, and more than 30% do so on Saturdays and Sundays[9]. Most of the stresses identified by old age psychiatrists relate to work overload or organizational structure and climate[10]. Many of these factors are equally applicable to staff working in geriatric medicine.

WHAT CAN BE DONE?

Appointment as a consultant brings long working hours and a number of different, often conflicting, roles (including responsible clinician, manager, budget holder, counsellor, researcher, teacher, team member, perhaps team leader) in various settings (wards, day hospitals, community and others). The result is role ambiguity, conflict and overload. Doctors could be better trained for the demands of consultanthood. The means by which consultants are supported, supervised and valued could be radically revised[11]. Individuals need to be able to change and develop their interests and work patterns over time, in order to allow re-energization. Time allocated to clinical work, teaching, research, family and other interests will vary at different stages of a person's working life. Organizations need to accept and support the evolving careers of their staff members.

Organizations need to accept and support the evolving careers of their staff members.

Developing and Maintaining Links between Service Disciplines: the Program for Organizing Interdisciplinary Self-education (POISE)

John A. Toner
Columbia University Stroud Center, New York, USA

The need for effective and systematic education of geriatric specialists in the field of psychiatry has been widely recognized[1]. Current shortages of general and child psychiatrists are gradually being surpassed by the shortages of geriatric psychiatrists[2]. The field of geriatric psychiatry education began to expand only recently, and this expansion was a direct result of funding of postgraduate specialty training programs in geriatric mental health by the National Institute of Mental Health[3].

Another major development in the field of psychiatry that has led to increased interest in, and expansion of, geriatric psychiatry training programs has been the evolution of subspecialization in geriatric psychiatry through Added Qualifications (Board Examinations) and the accreditation of geriatric psychiatry residency/fellowship programs. However, as the specialty field of geriatric psychiatry has evolved, it has become more apparent than ever that general practitioners, rather than geriatric psychiatrists, will provide the bulk of care to mentally ill older people. Although guidelines for developing curricula in geriatric psychiatry have been developed[1,3], these guidelines focus primarily on the clinical skills necessary for the psychiatrist or general practitioner to treat geriatric patients, and not on the leadership skills necessary for the psychiatrist or general practitioner to facilitate and lead the interdisciplinary healthcare team. The curriculum guidelines also neglect to emphasize the role of the geriatric psychiatrist as the key link between service disciplines on the mental healthcare team.

For some time, the interdisciplinary healthcare team approach has been well established in specialty areas, such as rehabilitation, surgery and dentistry; however, the fields of psychiatry and and general medicine, specifically geriatric psychiatry, have been slow to realize the important role of the geriatric psychiatrist as part of the mental healthcare team approach to care of the geriatric patient. The field has been even slower to recognize the central role the geriatric psychiatrist can and should play in facilitating cohesive team function and linking treatment goals of different service disciplines. The purpose of this chapter is to describe a model interdisciplinary team leadership training program, which exists within the curriculum of a geriatric psychiatry fellowship program sponsored by the New York State Office of Mental Health. This model program is unique in that it focuses on training geriatric psychiatrists in the skills required to develop, lead and maintain interdisciplinary treatment teams in inpatient and outpatient settings.

Schmitt *et al.*[4] indicate that the term "interdisciplinary teams" in healthcare settings has a variety of meanings, depending on usage. Thus, it is important to establish criteria that define the term. For the purpose of this chapter, we have adopted the criteria set out by Schmitt and her colleagues[5]. These criteria require at a minimum that the healthcare team: (a) includes a variety of disciplines in the care of the same patient; (b) encompasses a diversity of dissimilar knowledge and skills required to treat the patient; (c) plans care by establishing an integrated set of goals shared by the providers of that care; and (d) shares information and coordinates their services through a systematic communication process.

PROGRAM BACKGROUND

The interdisciplinary team training program described in this chapter is the outcome of 15 years of work devoted to the development of a durable, cost-effective method of linking and coordinating mental health services within the institutional setting. The program evolved, in part, from an educational philosophy that focuses on a participative model of self-education. The assumption is that the healthcare staff of an institution already have the technical skills required to function in their particular position, but need to enhance their understanding of how their roles in their particular discipline relate to the roles of other team members from different disciplines, and how the team as a whole relates to other staff and teams. A system by which the staff can work collaboratively to deliver effective treatment to patients is regarded as essential.

This concept was first applied in assessment training programs and subsequent related studies involving mental healthcare teams at state psychiatric centers in New York[6–8]. The results of these evaluation studies and the favorable response of staff to the interdisciplinary mental healthcare team leadership training[9–11] led to a request by the Deputy Commissioner of the New York State Office of Mental Health to adapt the program for implementation in other psychiatric centers throughout New York State. In subsequent discussions, it was determined that the training would be most successful and relevant if it was conducted with the key member of the mental healthcare team who most often is responsible for team leadership, namely the psychiatrist. In this way, a culture of learning would be established and the psychiatrist trainees would then go on to work on interdisciplinary treatment teams elsewhere, and bring with them to their new work setting this culture of learning. Thus, the psychiatrist trainees would

disseminate to other staff members from other disciplines the knowledge they obtained during the team leadership training. This adaptation of the original model program was applied to the development of the Columbia University Geriatric Psychiatry Residency and Fellowship Programs, which are sponsored by the Stroud Center and the Department of Psychiatry of the Columbia University Faculty of Medicine, Binghamton Psychiatric Center of the New York State Office of Mental Health. This program is accredited by the Accreditation Council for Graduate Medical Education. The Geriatric Psychiatry Residency and Fellowship Programs bring together the clinical resources of the Binghamton Psychiatric Center and the educational and clinical research resources of the Stroud Center/Center for Geriatrics and Gerontology of Columbia University.

Since its inception, the Geriatric Psychiatry Residency and Fellowship Programs has included, as a core ingredient of the long-term care component of the curriculum[12], the training of psychiatrist-fellows in the methods of interdisciplinary team leadership. Additionally, every fellow is required, during his/her fellowship, to develop and/or lead an interdisciplinary treatment team under direct and regular supervision of fellowship faculty.

PROGRAM DEVELOPMENT

Rationale

All clinicians need a good system for identifying patients' symptoms, making informed treatment decisions regarding the patients, and managing stress that is related to providing care. All members of the treatment team need practical tools to guide them in eliciting, classifying, recording, and interpreting information on patients' health status and functioning—in short, a system that will help them to evaluate each patient's status, identify the appropriate treatment, predict possible outcomes, and plan the patient's care. This system must also include methods to assist the interdisciplinary team in functioning as a team and managing their own stress.

A program designed to train interdisciplinary mental health care team members at psychiatric centers within the New York State Office of Mental Health was developed, implemented and evaluated[8,10]. The purpose of the program was to upgrade the functioning of the multidisciplinary/interdisciplinary mental healthcare treatment team and to train staff to identify and manage the stress that developed as a result of caring for older psychiatric patients, many of whom are demented. The Program for Organizing Interdisciplinary Self-education (POISE), the name by which the program is officially known, is a multidisciplinary/interdisciplinary approach to improving the assessment of patients in psychiatric hospitals and the treatment planning decisions based on those assessments. The program also provides training of staff in current methods of stress management. POISE currently focuses on the training of the geriatric psychiatrist as the central member of the interdisciplinary mental healthcare team.

The geriatric psychiatrist is a key figure in the treatment and management of geriatric patients in both inpatient and outpatient psychiatric facilities. The geriatric psychiatrist is also a core member of the interdisciplinary treatment team and is a key link between service disciplines on the team in psychiatric settings. Regardless of the level of functioning of the team, the geriatric psychiatrist is often viewed by team members as the primary care physician who is ultimately responsible for leading the team and thus coordinating the treatment of geriatric patients. However, most geriatric psychiatrists receive little or no training that will enable them to work effectively as a core member of the interdisciplinary team and key link between team members.

The geriatric psychiatrist and other members of the interdisciplinary team require special training to enable them to work effectively together[13,16]. Training, which can be accomplished either formally or informally on and/or off the unit, can be directed at facilitating and encouraging a team approach to patient care. This training must be durable in as much as it can be replicated throughout an entire system of care to achieve objectives; in that its effects last beyond the period of training; in that it concentrates on developing team cohesiveness and increased productivity; and in as much as it is based on teaching the team how to continue and maintain self-learning processes (including monitoring of own performance to achieve objectives). The training must be directed at a key member of the team (e.g. geriatric psychiatrist), who then goes on to train other members of the team. In this way, team functioning can continue, even in the absence of the facilitator, the geriatric psychiatrist.

The Columbia University Geriatric Psychiatry Residency and Fellowship Programs includes training in interdisciplinary team leadership as a core component of its training of geriatric psychiatrists. This training component, POISE, is described below. Details regarding the specific interdisciplinary treatment team training approaches used in the training of geriatric psychiatrists are given in Toner *et al.*[14] and Miller and Toner[15], who have outlined the steps in developing and implementing a geriatric team.

Program Description

POISE is a durable, cost-effective approach to teaching geriatric psychiatrists (i.e. residents and fellows in training) methods of self-learning which serve as ongoing tools for planning treatment for patients. It is durable and cost-effective, in as much as the geriatric psychiatrist, and ultimately other members of the interdisciplinary team, learn methods of effectively working with one another by collaboratively setting goals and arriving at appropriate treatment decisions for the patient. After the geriatric psychiatry resident/fellow receives core training in interdisciplinary team development and leadership, he/she is assigned to an existing interdisciplinary team, where he/she imparts the core training to the members of the team. The team then continues to apply these methods on an ongoing basis and the geriatric psychiatrist continues to provide guidance and leadership as the group leader/facilitator. This approach to staff training is untraditional because, instead of relying on conventional didactic approaches to learning or the charismatic qualities of the group leader, the core training focuses on teaching the geriatric psychiatrist the methods of self-learning in regard to assessment[16]. Geriatric assessment serves as the unifying theme of the training, because most staff conduct assessment in one way or another—including the nursing aides, who generally do not view themselves as assessors—and because most staff feel they need additional training in assessment. Furthermore, although most team members assess patient functioning, no single discipline considers assessment as their exclusive domain. In this way, while team members are organized and ultimately conditioned to focus on the theme of assessment, interdisciplinary conflict revolving around disciplinary territorial issues is avoided, since no one discipline or individual has exclusive rights to the theme. The theme of assessment also serves as a springboard for discussing more general group functioning issues.

In POISE, the concept of self-learning is applied directly to the training of the geriatric psychiatrist resident/fellow in a long-term care setting serving the elderly. Thus, the geriatric psychiatrist resident/fellow and other members of the interdisciplinary team are trained to develop their own skills and strengths in regard to the identification, classification and

treatment of patient problems, rather than superimposing a costly didactic approach which, at best, can expect to yield only short-term effects because of frequent staff turnover and administrative changes.

More concretely, the geriatric psychiatrist is trained in the methods of team leadership, using geriatric assessment as a central theme, and the methods of facilitating interdisciplinary team collaboration among the kinds of people associated with the chain of patient care, the treatment team. The geriatric psychiatrist also receives, as part of his/her core training, instruction in a method of developing with the team the universe of management decisions available to them in that particular setting (i.e. the Treatment Decision Guide). By using case examples, review of patient records, videotapes of case conferences, admission interviews, etc., the geriatric psychiatrist (as facilitator) and the team arrive at an understanding of good and bad management decisions, what problems exist in making treatment decisions, how these problems develop, what treatment options are (or might be) available, what methods team members use in arriving at appropriate treatment decisions, and what possible alternatives exist in arriving at a diagnosis. By establishing with the team the criteria that must be met in order to arrive at a particular treatment decision, the geriatric psychiatrist and other team members establish goals and objectives for any specific treatment decision available to them and discuss how assessment can be used to better link patient problems to the appropriate treatment decision. Through this process, the Treatment Decision Guide[14,15] is developed. This Treatment Decision Guide identifies the dynamic pathway for use of information regarding the patient in planning, implementing and monitoring treatment. The Treatment Decision Guide provides team members with a guide for using assessment and is also a useful, cost-effective and durable recipe for planning treatment.

Clinical Applications

POISE sensitizes the geriatric psychiatrist to the psychosocial problems that have a high frequency in the elderly long-term care patient population. It provides the geriatric psychiatrist with a program for upgrading the interaction process between interdisciplinary team members through group process exercises and lectures, which emphasize the role of the geriatric psychiatrist and other team members in assessing the well-being of patients and linking that assessment to treatment. The program then goes on to train the geriatric psychiatrist to lead teams and train other team members in team leadership.

POISE also improves the quality of staff interaction and team functioning by: (a) setting up systematic approaches and procedures for making appropriate treatment decisions; and (b) once this system has been set up, providing a device by which professionals and paraprofessionals relate to one another in operating the ongoing system themselves. This is done primarily through the use of the Treatment Decision Guide and Systematic Problem Solving. In addition, POISE enhances patient care by improving staff knowledge and skills in regard to assessment. This is accomplished through group exercises designed to build the geriatric psychiatrist's and other team members' skills in observing patients and formulating decision plans based on those observations. In this way, the geriatric psychiatrist is trained to be a facilitator, who provides the team with a mechanism by which the group does its own learning on an ongoing basis.

SUMMARY

The Program for Organizing Interdisciplinary Self-education, POISE[16], is one program that has demonstrated that the principles of interdisciplinary collaboration and team training can be applied successfully in a geriatric psychiatry residency/fellowship program[13]. The learning process involved in POISE covers the skills, knowledge and attitudes of team members regarding the following program components: team development, management, and maintenance; and program needs assessment.

POISE focuses on the training of geriatric psychiatrist fellows in the following areas[13]:

1. The role each member of the team plays in assessing the patient.
2. Linking each member's assessment to a treatment plan.
3. Systematic approaches and procedures for making appropriate treatment decisions. This includes methods of defining and negotiating team members' roles; case study approaches to prioritizing treatment goals; and systematic approaches to problem solving.
4. The Treatment Decision Guide (TDG): a guide designed by the interdisciplinary team members specifically for patient management in their particular institution, the TDG provides a key to arriving at available treatment alternatives in that institution.

After the geriatric psychiatrist is trained in POISE, he/she is trained in the method of teaching other interdisciplinary treatment team members the POISE method and thus provides the team members with the crucial techniques for maintaining the ongoing team themselves. Once the geriatric psychiatrist is assigned to the interdisciplinary team, the emphasis of the training is on shared leadership functions of all team members, with designated leaders, experiential learning to facilitate team functioning and problem solving, and ongoing orientation of new team members (to team objectives and norms).

Appendix—International Psychogeriatric Association (IPA)

Barry Reisberg (former IPA President) and Fern F. Finkel (Executive Director)
New York University School of Medicine, New York, USA

The International Psychogeriatric Association is a worldwide, multidisciplinary group of healthcare professionals dedicated to the advancement of mental health in the elderly and the field of psychogeriatrics.

The organization was proposed by Imre Fejer and Hans Reichenfeld in 1980, following a very popular course in psychogeriatrics that had been developed by Professor Tom Arie in Nottingham, UK. The organization's founding meeting was held in Cairo, Egypt, in November 1982. Subsequently, IPA congresses have been held every 2 years. Early congresses were held in Umeå, Sweden (1985), Chicago, USA (1987), Tokyo, Japan (1989) and Rome, Italy (1991). The organization has maintained these widely geographically dispersed settings for its congresses until the present time (Table 142.1). In its early years, the growth of the organization was shepherded by Manfred Bergener (Cologne, Germany), President and Sanford Finkel (Chicago, USA), Secretary–Treasurer. A measure of the influence that Sanford Finkel has had on the organization includes his unique role in having served as IPA President (Table 142.2), as well as Secretary–Treasurer and chair of many important IPA committees and task forces.

From the outset, IPA has been successful in contributing to major developments in the field of psychogeriatrics. The organization has done this in large part through its very successful conferences. IPA's Board of Directors has also contributed very significantly. Currently, there are 25 directors and five officers from around the world serving on IPA's Board. From the very beginning, the Board decided that no more than two directors can represent any single country. Consequently, IPA's Board is a disparate and geographically diverse group. Many of the outstanding scientific and medical leaders in our field have served on IPA's board. Examples include Sir Martin Roth (UK), Luigi Amaducci (Italy) and Kazuo Hasegawa (Japan). IPA has also, from the outset, had regularly scheduled regional meetings at intervals of approximately 6 months. These meetings have also been held in diverse locations around the world (Table 142.1). A great advantage of these meetings is that, unlike the IPA congresses, they are generally held in conjunction with a local organization with a neuropsychogeriatric interest. This has enabled IPA to have fertile interchanges with many local professional groups. These include joint meetings with ongoing local or regional groups, such as the Turkish Society of Psychogeriatrics, the Institute of Mental Health of Beijing Medical University, the Royal College of Psychiatrists' Faculty of Old Age and the Brazilian Association of Geriatric Neuropsychiatry.

Table 142.1 IPA congress and meeting dates and locations

November 22–25, 1982	1st Congress; Cairo, Egypt
October 18–20, 1984	Cologne, Germany
August 28–31, 1985	2nd Congress; Umeå, Sweden
September 5–6, 1986	Paris, France
March 26–28, 1987	Baden/Vienna, Austria
August 23–31, 1987	3rd Congress; Chicago, USA
April 28–29, 1988	Lausanne, Switzerland
August 25–27, 1988	Budapest, Hungary
May 18–19, 1989	Modena, Italy
September 5–8, 1989	4th Congress; Tokyo, Japan
September 21–22, 1990	Gothenburg, Sweden
April 2–5, 1991	Cambridge, UK
August 18–23, 1991	5th Congress; Rome, Italy
February 15–17, 1992	San Francisco, USA
October 29–30, 1992	Lille, France
April 16–18, 1993	Toronto, Canada
September 5–10, 1993	6th Congress; Berlin, Germany
June 5–8, 1994	Amsterdam, The Netherlands
February 17–20, 1995	Cancun, Mexico
October 29–Nov 3, 1995	7th Congress; Sydney, Australia
March 9–10, 1996	New Delhi, India
October 4–5, 1996	Reykjavik, Iceland
April 25–27, 1997	São Paulo, Brazil
August 17–22, 1997	8th Congress; Jerusalem, Israel
May 21–23, 1998	Istanbul, Turkey
September 13–18, 1998	Munich, Germany
April 12–14, 1999	Beijing, China
August 15–20, 1999	9th Congress; Vancouver, Canada
April 4–7, 2000	Newcastle upon Tyne, UK
October 13–15, 2000	Pôrto Alegre, Brazil

B. Reisberg, USA (1997)
E. Chiu, Australia (1999)

The regional meetings and congresses have been the lifeblood of the organization and have brought together diverse professionals who are interested in our field. These include geropsychiatrists, neurologists, geriatric general and family

physicians, psychologists, geropsychiatric nurses, social workers, occupational therapists and others with an interest in our field. Presidents of the organization have until now been drawn from the disciplines of psychiatry and geriatric medicine.

Although these meetings and congresses have been sufficient to serve the growth of our organization, IPA has also created initiatives which have independently served our discipline. One of these initiatives concerns the coveted IPA Research Awards in Psychogeriatrics. The research awards were conceived through the vision of Manfred Bergener and were supported through the generosity of Bayer AG for the first decade, from 1989. These awards, for which submissions are solicited from throughout the world, are given for the best unpublished research submission. Since its inception, the Research Awards Committee has been chaired by Barry Reisberg, with referees from many nations who devote their time, energy and expertise to the exceedingly rigorous review process for these awards.

Winning papers over the course of the years have provided a significant contribution to the body of knowledge and progress in our field. For example, in the first Awards in Tokyo, 1989, subsequently famous research studies on behavioral and psychological symptoms of dementia (BPSD) by Alistair Burns (UK) and on reduction of Alzheimer's disease caregiver stress by Henry Brodaty (Australia) were awarded, in addition to seminal research by Barry Rovner (USA) on agitation in nursing home settings in the USA. Each of these award-winning research entries provided a stimulus for numerous subsequent papers and, more importantly, major changes in the structure of our field. For example, in part as a result of Alistair Burns' work, we now know much more regarding the nature of BPSD and pharmacologic and non-pharmacologic treatments of BPSD. As a result, in part, of Henry Brodaty's award-winning research, Alzheimer's organizations and associated support groups have now proliferated throughout the globe. Barry Rovner's findings led, in part, to changes in the quality of care provided to nursing home residents.

This astoundingly important work, singled out for accolades in IPA's first series of research awards, has resulted in commensurate effects on the careers of these scientists. For example, Alistair Burns is currently the President-elect of IPA and Henry Brodaty is presently the medical director of Alzheimer Disease International. The research awards have remained similarly successful from 1989 to the present, and have clearly not only stimulated the growth of our field but also served to advance the mental health quality of the elderly.

Another modality that IPA has chosen to coalesce growth in our field has been the convening of special meetings. These meetings have typically brought together leading scientists, leading clinicians, government officials, representatives of regulatory agencies and others to coalesce knowledge around a particular subject in our field. For example, a meeting was held in 1994 on "Methodology for drug trials in mild, moderate and severe Alzheimer's disease". This meeting, held in New York, helped to stimulate the approval and understanding of pharmacologic treatments for Alzheimer's disease which have now been approved in many nations around the world.

Another timely special meeting concerned behavioral and psychological symptoms of dementia (BPSD) in 1996. This meeting stimulated worldwide trials of drugs for the treatment of BPSD and subsequent demonstrations of efficacy. An update special meeting on BPSD was held in 1999. Yet another special meeting, which was held in Geneva in 1996, pulled together current knowledge regarding the diagnosis of Alzheimer's disease from diverse clinical and psychologic, electrophysiologic, neuroimaging, pathologic and biomolecular perspectives. This meeting helped foster the understanding that Alzheimer's disease, like all other major illnesses, is a diagnosis of inclusion as well as of exclusion.

IPA has published a journal, *International Psychogeriatrics*, since 1989, which is an Index Medicus publication and is a leading organ for research and information regarding worldwide activities in psychogeriatrics. Apart from regularly scheduled quarterly issues, *International Psychogeriatrics* has published groundbreaking and syncretic special issues. The special issues have included the proceedings of IPA's special meetings as well as comprehensive issues on other topics, such as a special issue on suicide in the elderly.

Another important publication of IPA is the *Bulletin*, a newsletter which serves as a less formal organ of communication for psychogeriatricians around the world. The IPA also publishes modules, pamphlets and slides on topics of special interest, such as BPSD. The publications further serve IPA's broad educational mission.

Other special and noteworthy activities of IPA include an international visiting junior scholar pilot program, sponsored by Pfizer, which enabled junior psychiatrists and neurologists from less financially endowed research nations to visit wealthier research institutions. For example, physician scholars from Argentina, Brazil, PR China, ROC Taiwan and Russia, were able to work at research centers in the USA, UK and Australia and absorb the most up-to-date methodologies for scientific research.

Yet another important initiative of IPA is its affiliate organization program, which is enabling regional and national organizations to have more ready access to international opportunities and resources and also enable IPA to reach physicians at the "grass roots" level. Equally important in terms of IPA's individual reach is its excellent website (www.ipa-online.org).

Apart from the activities listed in this brief summary, IPA has been involved in numerous other activities and communications in psychogeriatrics. The net result of these activities at the present time was reflected in part by IPA's outstanding Ninth Congress, which was held in Vancouver in 1999. This meeting was the largest meeting ever held in the field of psychogeriatrics. It brought together colleagues from 50 countries that represent IPA's diverse constituency, currently encompassing 75 of the world's nations.

In coming years, IPA seeks to further develop governmental consulting activities in psychogeriatrics, and to further develop its website and affiliate organization program, while maintaining, expanding and improving upon its numerous other activities on behalf of our field.

In summary, through a series of outstanding initiatives and activities, IPA has served the growth of psychogeriatrics worldwide for the past two decades. The goals of these activities continue to be improved mental health as people age, and consequently improved health more generally, throughout the world.
